It is stated in an Amsterdam paper, that a farmer in Herkimer, has saved from the worm, an extensive wheat crop, by fumigating with brimstone for a few days, when the wheat-fly most abounded, while all around him was swept as with the besom of destruction. He employed 100 lbs. of brimstone to a field of 100 bushels sowing. The brimstone was melted, and strips of old woollen cloth dipped in it, which were fixed on sticks in different parts of the field, and particularly on the windward side, at evening. The smoke and gas of the sulphur, which is offensive or destructive to the insect, thus every where penetrated the standing grain, and preserved the crop.

The Yankee Farmer advises, that burning or smoking with pine knots, has been found efficacious. The mode of operating is, to brush the tops of the grain with a long pole, carried across the field in a horizontal position, which causes the fly to rise,—a strip of board, raised somewhat above the pole, is perforated with holes, into which are placed splinters of fat pine, which are lighted—and the flame scorches the wings of the flies as they rise.

Of these expedients, the first appears to claim the preference; and we think it would prove efficacious in protecting young fruit from the curculio, were brimstone employed in this way, occasionally for a few days, to fumigate the branches of the trees; the young fruits would become so impregnated with the fumes of the sulphur, as to render them obnoxious to the insect.

A writer in the Farmers' Magazine, says he practises fumigation to preserve his young turnips from the fly. He collects the weeds on the farm, lays them in heaps round the field, and on the appearance of the fly, the heaps to windward are set on fire, brimstone thrown upon them, and the offensive smoke is wafted over the crop. This is repeated till the turnips attain their second leaves, and is always successful.

English Agricultural Society.

The subscription to this society, now organizing in Britain, embraces the names of nearly 100 members of parliament, and a great many of the nobility and gentry, of all political parties. Ninety individuals have subscribed each £50, ($222,) to constitute them life members or life governors; and 115 others have subscribed £5 ($22.20,) annually to constitute them governors—ordinary members pay £1=to $4.44 per annum. This is but the commencement. Thus will a fund be secured in the outset, from other than ordinary members, of more than $22,500. We should like to see this spirited example imitated by the capitalists and statesmen of the United States. It would form a new and auspicious era in our history, and evince at once a high feeling of patriotism, and a discriminating judgment in the display of it.

Beware of Loco-Foco Matches.

A boy was bringing into our room some parcels of these matches, when a bunch, wrapped in a paper, slipped from his hand, and fell on the carpet; the friction occasioned by the fall instantly ignited the bundle. We doubt not but many recent fires have been caused by the accidental ignition of these phosphorated matches. Every house-keeper should see that these matches are securely kept in metal or earthen, and apart from all combustible materials. Another modern improvement—the portable furnace—we doubt not, has led to immense losses by fire.

On the Causes and Prevention of Rust or Mildew.

The Quarterly Journal of Agriculture, to which we are indebted for much valuable matter to fill our pages, has a lengthy article on smut, canker, and rust or mildew. Having published in our two last numbers, several articles on the causes and means of preventing smut, we shall now give so much of the article from the Quarterly, as is descriptive of the rust or mildew, the ascertained cause of the evil, with some suggestions for its prevention, omitting the speculative opinions which have prevailed on the subject, and their refutation by modern writers and experience.

DESCRIPTION OF RUST OR MILDEW.

"Rust first makes its appearance on the upper leaf, and then on the lower leaves and the stem, in the form of small white spots, scattered irregularly like spots made by rain on new cloth. These spots gradually increase in size and number, and assume a reddish tinge, and at length form a sort of dust-looking powder, of an ochre or orange yellow, little cohesive, and without smell or taste, and therefore very different from canker or smut. It stains the fingers yellow, as well as the clothes of those who walk among the affected corn.

"The dust-like substances of the rust originates beneath the outer bark or epidermis of the plant, which it raises up, renders thin, and at length cracks and bursts through. When examined by the microscope, it presents a congeries of egg-oblong bodies, some of which have projections almost like tadpoles or *powheads*, though they are not animated.

"Wheat is attacked with the red rust at different periods of vegetation, but more particularly when in the ear. When the rust seizes young plants. they are said to suffer less than when they are more advanced, often recovering vigor before blooming; whereas at a later period they sustain irreparable damage, and crops which promise well are often in a short time rendered comparatively worthless. In this case the texture of the leaves is disunited, and presents only longitudinal fibres of a brown colour, while the joints and the tubes of the straw between are blackened, as if they had been scorched by fire, the growth ceases, a portion of the ear bceomes yellow, another portion remains green, and the grain shrivels up in the husk without attaining maturity.

"The evil, however, is rarely carried so far as this, and the yellow spots of rust become chocolate-brown or black, without disorganizing the portions of the plants where they occur; and the Abbe Tessier says he has seen, after heavy rains, the clothes of the reapers stained with this black substance of the rust as if they had been dipt in ink. But though the plants are not disorganized, the flow of the sap is interrupted, the ripening of the grain is prematurely hastened, and it is hence light, containing a small proportion of farina, while the straw is bad. Sometimes the rust only leaves a yellow powder on the husks and upper end of the grains, taken by Fontana and others to be a different species.

"Sometimes rust prevails so extensively, that few fields escape; but for the most part it is observed in fields sheltered from the north winds by walls, hedges or woods, or where vegetation is very luxuriant, on account of fresh soil or abundant manuring. Sometimes one part of the field escaps while the other is attacked; sometimes the chief plants, and at other times the side shoots tillering from them are affected; and sometimes rusty and sound plants grow from the same root."

OF THE INFLUENCE OF THE BARBERRY BUSH.

Although it is conceded, that the farmers of England, and on the continent, generally ascribe the rust, in a measure, to the infection which spreads from the barberry bush, and that this notion is sometimes strengthened from the rust appearing in patches and strips among the grain, as if it had been carried thither by the wind from the barberry bushes—and although this opinion was sustained by Sir Joseph Banks,—the writer nevertheless considers the theory as fallacious, and quotes an anonymous authority in saying, that the rust which is found on different trees and plants is altogether of distinct and separate species.

"*Dutrochet's discovery of the mode of growth in funguses.*—In a damp cellar where wine was kept, M. Dutrochet, one of the most original observers of the day, remarked, about two or three years ago, a white looking net-work of fibres, which previous botanists had described as a species of crow-silk, (*Byssus.*) Being struck with its peculiar manner of growth, he watched it with careful attention, and got M. Tupin, probably the best botanical draughtsman in Europe, to take drawings from it in every stage of its growth. The general result was, that the supposed crow-silk was not, as had been supposed, of the genius *Byssus* at all, but the genuine stems, hitherto known as such, of a mushroom, (*agaricus crispus*, Tupin,) the mushroom itself being the fruit only, and not as hitherto believed, the whole plant. According to this view, then, it would be as correct to consider a bunch of grapes, with their fruit-stalk, a complete plant, as the fruits termed mushrooms, puff-balls, or puddock-stools, all these being but the fruits of plants generally growing under ground, in the form of small white or grey fibres of net-work, and termed improperly by gardeners, *spawn*, indicating that it is the seed of mushrooms, whereas it is the genuine plant.

"M. M. Dutrochet and Tupin, further discovered, that the seeds, or, as they are termed by botanists, *sporules*, consisting of minute globular bodies, are contained in the cells of fungus fruit in prodigious numbers, and they succeeded in observing these germinate and produce young plants like their parent. There therefore cannot remain a doubt, that funguses are produced from seeds in the same way as all other vegetables, though these seeds or sporules are exceedingly smaller than those of green plants—being as subtle, Mr. Fries remarks, sometimes as smoke.

"Contrary, then, to what takes place in regard to the eggs of insects, which are too heavy to be carried about by winds, and if they were lighter, are generally, when laid, glued to the substances destined for the food of the young, when hatched, the minute, light, subtle seeds of funguses and mosses are floated about in the air with the gentlest breeze, and in this way diffused over immense tracts of country, in numbers altogether countless. The discovery of M. Dutrochet is, therefore, of the greatest interest in making us acquainted with the economy of Providence in the propagation of fungi, hitherto altogether mysterious.

"What we term smut, canker and rust, are, according to this discovery of M. Dutrochet, only the fruit of particular funguses, the plants of which they are the fruits being hitherto undescribed and unknown, but which must be sought for in the form of delicate fibres, probably transparent, and probably difficult to see in the textures of the corn affected with those destructive parasites.

"It forms no objection to this view, that the fibres of these funguses have not been seen except partially by Bauer and Ad. Brongniart, in their microscopal researches, for M. Dutrochet further found, that when the fruit of the plant observed by him (*agaricus crispus*,) sent up its foot-stalks, (*stipes*) it became partially detached from the main plant, and independent of it for its future nourishment, the fibres of the main plant indeed becoming exhausted of substance, and disappearing as in what were previously supposed to be the roots at the base of the fruit-stalk in the edible mushroom, which supposed roots are the fibres of the main plant, partly exhausted of their substance by the nourishment of the fruit."

The editor of the Quarterly here details some ingenious experiments of M. Fee, to ascertain the manner in which plants become affected by fungi, or the mode in which the sporules are propagated. M. Fee infers from the result of these experiments, that the seeds or sporules of the fungi are sucked up with the moisture of the soil, by the tips or spongioles of the root fibres.

ASCERTAINED CAUSE OF RUST OR MILDEW.

"The rust, and various sorts of what are termed mildew, are all caused by small fungi, such as the tuft-brand, (*Peccunia graminis*, Persoon; or *uredo fumenti*, Sowerby,) and the linedebrand, (*uredo linearis*, Persoon; *u. largissema*, Sowerby,) which do not differ so much in the injuries which they produce as in their mode of growth and appearance, as has been already described.

"The history of the red rust need not detain us, as it has been long well known from the very good account given of it by Sir Joseph Banks, with most admirable drawings, by M. Bauer. The opinion, however, which Sir Joseph seems to adopt, is, not that the seeds of the rust fungus get into the corn plants by the tips of the roots, but by the pores on the leaves and stems, being carried there by the winds, and caused to adhere by the moisture of dew or rain. When once entered into the pores, he says—'they germinate, and push their minute roots, no doubt (though these have not yet been traced,) into the cellular texture beyond the bark, where they draw their nourishment by intercepting the sap that was intended by nature for the nutriment of the grain. The corn, of course, becomes shrivelled, in proportion as the fungi are more or less numerous on the plant; and as the kernel only is abstracted from the grain, while the cortical part remains undiminished, the proportion of bran in blighted corn is always reduced to the same degree as the corn is made light. Some of the last year will not yield a stone of flour for a sack of wheat.' "—*On blight in corn.*

PREVENTION OF RUST.

On this branch of the subject, we find little to copy, that, in our opinion, is worth the pains. The writer adopts the opinion, that the seeds or sporules of the fungi, smut, canker and mildew, are disseminated in myriads over our fields—that these seeds are carried into the soil by the rain, and that they enter the plant by the tips of the roots. The prevention recommended is paring and burning, or copiously liming; the first of which he thinks will destroy wholly, and the other partially, the vital power of the fungi.

We dissent from the opinion of Fee, adopted by the Quarterly, that the seeds of the fungi enter the plant by the root, and are disposed to believe with Sir Joseph Banks, that the seeds of the rust-fungus get into the plant by the pores of the leaves and stem. And we will offer some reasons for this belief. 1. The prevalence of rust depends much upon the temperature and humidity of the season when it prevails. If the season is moist and hot, and the atmosphere calm, this disease most abounds. On the contrary, if it is cool and dry, and northern winds prevail, we see very little of it. 2. The prevalence of rust depends much on exposure and luxuriance of growth. If the field is much sheltered from drying winds, the air in a measure stagnant, or the growth of straw luxuriant, as on the site of dung heaps, the rust-fungus is pretty certain to appear; but it seldom shows itself in open exposures, where the growth of the straw is moderate, or has not been stimulated by recent or too abundant manures, except the season is hot and humid. Upon M. Fee's theory, all seasons and all soils would produce it alike, provided the soils were once impregnated with the seeds. Its appearance only in certain seasons and in certain locations, can readily be explained on Sir Joseph Banks' theory. In the seasons and locations in which rust is most prevalent, the atmosphere is comparatively light and stagnant, and the epidermis of the grain soft, spongy and moist. Now assuming what M. Fee asserts, and we have no reason to doubt his correctness, that the seeds of the rust-fungus are as subtle as smoke, they might readily be wafted by this light atmosphere to the leaves and stems of the grain, which would be in an excellent condition, under such circumstances, to receive and nurture them. But when the atmosphere is dry, and the air in brisk circulation, its specific gravity is too heavy for these seeds to float in it, and the leaves and stems of the grain are less fitted for its reception. When the atmosphere is light, smoke lingers upon the earth's surface; when it is dry and heavy, smoke immediately rises to the upper regions.

If our views are correct, liming, or even paring and burning, would effect little towards the prevention of rust and mildew. The best preventives, in our opinion, are, to apply the manure intended for wheat, to a previous hoed crop, that the heat of fermentation, which causes a strong and protracted growth of straw, may have subsided; and to sow upon dry grounds, or if flat and retentive, to lay the land in ridges, that all surplus water may readily drain off. These precautions, added to clean and thorough tillage, we think, will be as efficacious as paring and burning. Liming wheat lands, we have no doubt, is beneficial in many respects; but that it will prevent rust, we have no facts before us that will justify us in asserting.

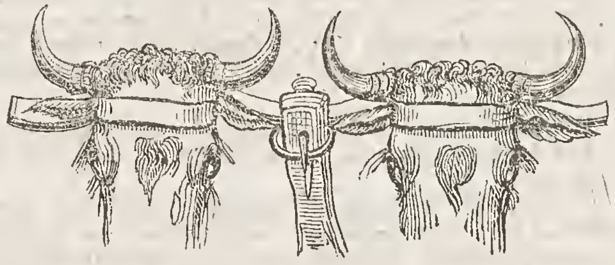
Ox Gearing.

The communications which we have heretofore published, from Mr. Allison and Mr. Woodruff, on the subject of ox gearing, have given an interest to the subject, which we trust may lead to some improvement in the matter. We feel assured, that the common mode of gearing oxen is a bad one, and that it may be modified with advantage to the animal and his master.

The Spanish mode of gearing seems to be the same as that practised in Portugal, and strongly recommended by Lord Somerville. The principle of draught depends, his lordship justly observes, on the joint power of the neck and base of the horns. The Portuguese, or Spanish mode, has been successfully tried in Ireland, by Lord Shannon, who found, that harnessed in this way, two oxen were able to draw, with great ease, *three tons* in weight.

We have deemed this matter of sufficient importance, to procure a cut to be made, representing the Spanish or Portuguese mode of gearing oxen, which we give below. We hope this may induce a fair trial by some of our spirited farmers; and if it should do so, we shall be very happy to be apprised of the result.

[Fig. No. 51.]



Successful Mode of Preserving Milk at Sea.

In November, 1836, a part of the conductor's family being about to sail for Europe, a dozen bottles of milk were prepared for their use, in the following way: The milk was drawn from the cows immediately into the bottles, the bottles well corked, and the corks secured with wire. The bottles were then laid into a kettle, upon some straw, the kettle filled with cold water, and the water heated to the boiling point. The milk was used on the passage, perfectly sweet, except one bottle, which lay in a chest unnoticed till it reached Ireland, and it was then found to be as sweet as when it was bottled at Albany.

A Convention of Farmers,

To wit: two from Connecticut, one from Georgia, one from the District of Columbia, two from New-Jersey, fourteen from the state of New-York, three from Massachusetts, two from Vermont, two from Ohio, one from Virginia, two from Pennsylvania, one from Upper Canada, one from Maryland, and one from Michigan, together with the conductor of the Cultivator, in all thirty-five individuals, met in Albany in May last, for mutual instruction in the business of husbandry,—to communicate and obtain useful information in their business. The meeting was one of great interest, and many facts were detailed, calculated to benefit each individual member, and to advance the public interest. It affords us pleasure to add, that like meetings have been, and will continue to be held monthly, and that some twenty thousand readers are receiving benefit from these monthly deliberations. Now, reader, all this is matter of fact, save that the individuals did not appear in *person*, but sent to the conductor their information and inquiries by letters, which were faithfully recorded in our June number. And is the information less valuable, by being written with care, and printed, so that it may be preserved and referred to, than it would have been if delivered by word of mouth, and liable to be forgotten and lost? We think not. We invite farmers then to profit by this concentrated knowledge of their brother laborers, by becoming patrons to the Cultivator, which promulgates it, almost without money and without price.

What is Book Farming?

The editor of the Quarterly Journal answers the question as follows:

"Book farming, we know, is not in favor with farmers, otherwise we should find admittance into *every* farmer's library, and every farmer [in Scotland] has a library. But although we know, and therefore admit, that no man can be made a farmer by book, we cannot admit that the best farmer cannot, may not, at a time, find useful hints in a book.—The best farmer cannot know every article of practice which is followed in every part of the country; and as most practices are discovered by what is called chance or accident, it is clear that the discovery cannot generally be made known until it is disseminated abroad. A farmer who travels, appreciates the information which he receives in conversation with farmers, and by observation of field labor. Such a farmer possesses advantages over him who always remains at home, that is, within the circle of his markets. Now the object of an agricultural book, and particularly of an agricultural periodical work, is, at stated times, to carry hints, suggestions or discoveries, important or unimportant, to the home of the farmer, that he who loves to stay at home may possess the advantages of him who at times travels abroad, and that he who travels abroad may compare what he has seen with what he reads, and decide which practice is best suited to his particular purpose; or perhaps when comparing the hints of others, he may himself discover a practice superior to them all. In this manner a good agricultural work is the means of disseminating through the country practices which would be confined to the district which gave them birth. Its principal aim should be to be a *good* work, that is, replete with suggestions of good sense, and with confirmations of experience. The collection and presentation of these desiderata, is attended with much trouble and expense, and unless the labor is appreciated and encouraged, it is impossible to use the means to collect the most valuable kind of information for presentation."

The Fair of the American Institute,

It will be remembered, commences at Niblo's garden, New-York, on the 15th inst. and will probably continue ten days or more. These fairs have done much to call forth and to publish, the inventive genius and skill of our countrymen, and to excite industry and emulation in the productive classes of the community. They deserve the countenance and support of every well wisher to the prosperity and independence of our country, and we trust they will command them.

Draining averts the effects of Drought.

That is, we mean to say, that grounds naturally wet, suffer more severely from drought *before*, than they do *after*, being thoroughly drained. The presence of standing water on a soil, even for a short time, tends to render it close and compact; and when the water evaporates or subsides, it becomes baked and very hard. On the other hand, if water merely passes through a soil, as it does where the subsoil is porous, or where there are sufficient under-drains to receive and convey it off, the earth remains light and pervious to the beneficent influences of heat, air and dew, from above, and to the capillary attraction of moisture from below,—a highly beneficial process to the crop, and the advantages of which depend much upon the porous condition of the surface stratum; and this in turn, as we have observed, is most porous where there is a ready outlet for all excess of water. In a field, last year, we lost nearly an acre of potatoes, on the slopes of a ravine, the soil being wet in the spring upon, and later under the surface. The water was partly from the surface, and had settled down upon an impervious stratum, and partly from spouts, which apparently rose from below the impervious stratum; it found egress on the slope of the ravine, or at its base, and saturated the whole soil to extreme wetness in spring. But when the season became dry, and the sources of supply in a measure exhausted, the surface soil became almost as hard as a brick-bat. In the fall, we constructed under-drains, with tile, so as to catch and convey off the water, before it came within two feet of the surface, and planted the ground with corn the present season. The crop upon these strips looks as well as in other parts of the field, has received no injury from drought, as the soil, instead of being hard baked, as it was last year, is comparatively loose and porous.

Under-draining becomes more and more requisite upon flat or impervious soils, as they are subjected to culture. New lands abound greatly in vegetable and ligneous matter, which impart a comparative lightness and porosity even to stiff clays. But as these lands are subjected to tillage, and the exhausting influence of crops, the vegetable matter diminishes, and the soil itself becomes more compact and adhesive, according to the good or bad husbandry which is adopted upon it. We know of a district in

Vermont, which, within our recollection, had a fine kind wheat soil, abounding in vegetable matter.—The vegetable matter has become exhausted by bad management, and the soil thin and compact; and as it rests upon hardpan, impervious to the surface water, it is no longer fit for tillage crops, and cannot be rendered fit for them, till it is relieved from its excess of water by under-drains, and kept under a more enlightened—a more scientific system of management. Such, we are pretty confident, will be the condition of many districts of light land in the yet fertile west, if timely resort is not had to under-draining, to manuring, and to alternating crops.

Effects of Alkali in preserving Wood.

The antisceptic properties of alkali, in preserving wood from rapid decay, must have been witnessed by most persons, in the boards and timbers about asheries, lime-kilns and the depositaries of lime. Its effect seems to be to neutralize the mucilagenous matter of the wood, whether in a dry or moist state, the tendency of which, heat and moisture being present, is to bring on fermentation, and consequent decomposition; while at the same time it seems to exclude, in a great measure, the free access of water into the pores of the wood. Our attention was first directed to this subject, by seeing, near Bordentown, N. J. a large vat filled with lime and water, or lime water, in which were immersed a great number of timbers, intended for the cross-timbers of a rail-road; and more recently by a communication in the Farmers' Cabinet, on the preservation of the roofs of buildings, by soaking the shingles in lime water. It is not, it seems, the insoluble parts of the lime, which is efficacious—for these rather obstruct the escape of prejudicial moisture from the wood—but it is the caustic alkaline solution of the lime—the liquid resulting from pouring water upon fresh burnt or recently slaked lime, that constitutes the antisceptic, and that powerfully arrests the decay of woody matter.

The writer of an article in the Cabinet, whose name we would creditably record, had he not been deterred, we fear by a false modesty, from giving it to the public, directs, that for saturating shingles, with alkali, an elevated box should be made, to mix the lime and water, so that the lime-water, when suitably prepared and clear, can be drawn off into a lower box, in which the shingles are placed upon their butt ends, so that that portion of them, which, when laid, is to be exposed to the weather, shall be completely saturated with the lime-water, which will require some hours. We would suggest that the entire shingles be immersed in the liquid, as the part not exposed to the weather, is also liable to decay.

White-washing with lime, the wash being impregnated with salt, has long been recommended by Mr. Coke and others, as a preservative to the wooden coverings of buildings, fences, &c. And it has this further to recommend it, that it promotes cleanliness and health, and is, withal, in the absence of paint, ornamental.

It is a matter of some importance, that the lime used in these processes, and it may be used to advantage for many other rural purposes, should be in a caustic state, that is, fresh burnt and well burnt; and that it be used as soon as practicable after the preparatory process is completed, as its effects, in destroying vermin, removing infection, or preserving wood from decay, depend upon its alkaline properties, which are rapidly diminished by exposure after it comes from the kiln.

Experiments in Manuring Turnips.

S. W. Smith has given to the public, in the Farmers' Cabinet, the result of an experiment with various manures upon his turnip crop, which are worth recording and remembering. He divided an acre of land into four equal parts, and gave to No. 1 a dressing of common stable dung; to No. 2, an extra quantity of compost manure; to No. 3, ten bushels of lime and two and a half of wood ashes; and to No. 4, two bushels of bone dust. They all escaped the fly, and were treated alike. They were sown the 15th and 16th June, and harvested the 10th November. The product was as follows:

No. 1	yielded	98	bushels	= to 390	per acre.
No. 2	"	124	"	= to 496	"
No. 3	"	185	"	= to 740	"
No. 4	"	213	"	= to 852	"

Pitts's Grain Separator and Cleaner.

This machine was patented in June, 1837, to J. A. & H. A. Pitts, of Winthrop, Maine, and of course its merits or demerits can yet be but partially known to the American farmers. We had heard it highly spoken of; but as hearing is not seeing, and as it is our practice not to recommend any new implement till we are satisfied of its utility, we have waited for ocular demonstration before we would venture to join in its praise. But now, having seen it in operation some days, on our premises, we are prepared to give it our unqualified approbation, as an excellent machine for the purposes intended.

It is a thrashing machine and fanning-mill combined. It thrashes, separates the straw from the grain, and cleans and delivers the latter, in the best order, for the sacks or bags—*in one operation*. It may be constructed for the power of one horse or more, though usually adapted for two horses, attached to an endless chain power, though it may be attached to other horse or propelling power; and the whole is so portable, that it may readily be transported, horse-power and all, by a two-horse team, and put in operation on a twelve foot barn floor. The cylinder and bed are of cast iron, the former rendered doubly secure by strong iron bands. The teeth are wrought iron, secured by nuts, are not liable to do injury if broken, and are readily repaired. This we saw verified: a sickle, which had been carelessly left in one of the sheaves, passed undiscovered into the thresher. The sickle was cut into five pieces, and the handle slivered. The machine was immediately stopped, and the cap taken off, when it was found that one tooth was spoiled, and two or three others somewhat bent, the whole of which were replaced or repaired in a few moments. The fanning-mill may be detached in two minutes, and used separately. The whole of the machinery is substantial, not liable to get out of order, and may be readily repaired.

As to the quantity of grain which this machine will thresh and clean, the patentee assures us, that 100 bushels of wheat or rye, or 200 bushels of oats, is a fair day's work with a machine of two horse power; and the numerous certificates which he has, from respectable farmers in Maine, Massachusetss and New-York, fully sustains him in this declaration.

There are two prominent advantages in this machine, over others that we have seen in operation, viz.

1. It thrashes, separates the straw, and perfectly cleans the grain, at one operation, demanding only the additional labor of a man to bag the grain as it comes from the machine. And,

2. It may be used any where—under cover during rain, or in the open field during fair weather, as there is no scattering or loss of grain even in the field. This we consider an important advantage in the great grain-growing districts of the south and west.

We are happy to add to our testimonial of approbation, the like testimonials of the Rev. H. Colman, and and of Messrs. H. Grove and C. N. Bement, who witnessed the operation of the machine at our place, and who fully concur in the above statement.

The price of the machine alone, at the manufactory, in Winthrop, is stated to be $110, and including the horse power $200. Address J. A. or H. A. Pitts, at the above place.

Notices of Correspondents.

Blight of the Plum.—Roswell M. Lawrence, of Catskill, assures us that he has found a cure or preventive of the canker or blight in the plum tree, in a strong decoction of tobacco, made by boiling the tobacco in water. He washes with this the excresences, on their first appearance in a green state, and applies to them some of the tobacco. He has tried the remedy in three instances, in all of which, he says, he has succeeded. The disease is undoubtedly caused by an insect, which the tobacco destroys; but we should doubt if the tobacco would heal and restore to health and vigor the diseased wood.

Improved Fence.—The following paragraph should have been inserted in Mr. Allison's communication in our last:

"In comparison with the post-and-rail fence, the *improved* has two important advantages—by avoiding, first, the ruinous necessity of spoiling the rails by splicing or fitting the ends into the holes of the post, side by side; which splices decay long before the rail has done its service. And, secondly, the difficulty of replacing a post or rail which gets broken by either accident or decay. Stakes having two supporters in the ground, which prop each other, also stand *firmer* than a post, where the ground is soft. I think these establish its superiority to the post-and rail."

Silk Culture.—E. D. Cotton, asks our advice and direction, in regard to the silk culture in Michigan. Mr. C. will find numerous publications on this subject in the book-stores. The Silk Culturist, published at Hartford, Ct. and the American Silk Grower, published at Burlington, N. J. are almost exclusively devoted to this subject. Our advice upon this matter may be seen in No. 1 of vol. iii. of the Cultivator. We think it a business in which some will succeed, and some fail; and that success will, in a great measure, depend, as in every other employment, upon the intelligence and economy with which it is managed.

Watermelons.—The twenty-four seeds received from Mr. Poullain, of Georgia, all grew, and produced the best crop we ever grew of this fine fruit—some weighing twenty-five pounds. The *Mountain Sprout* is of peculiar fine and delicate flavor. Seeds will be distributed at the meeting of the State Agricultural Society in February.

Agricultural Fairs.—The propriety of publishing in the Cultivator notices of the annual agricultural fairs and exhibitions, held in the northern and middle states, has been suggested by a highly respectable correspondent. We thank him for the suggestion, and highly approve of the plan. As it is now too late to notice them for the current season, we will endeavor to do it another year; and to enable us to do so, we respectfully solicit information, in time for our July or August number, 1839.

Agricultural implements, &c.—W. Dinn, No. 17 Common-street, New-Orleans, seedsman, desires to buy, or sell on commission, any useful agricultural implements that may be adapted to a southern latitude.

Saxony Sheep.—Our friend, H. D. Grove, advertises forty bucks and sixty ewes, of the pure Electoral Saxon race. We believe there is no purer flock of Saxons in our country than Mr. Grove's, and we can speak of the owner as a gentleman of strict probity and honor. Address Mr. Grove at Buskirk's Bridge, Washington county, N. Y.

Lincolnshire Sheep.—A letter from our friend D. Cliff, of Carmel, Putnam county, says—"I can now, with the utmost confidence, state, after a trial of three years, having now a third generation of lambs, in all about one hundred and fifty of the cross and full bloods, that they have exceeded my most sanguine expectations. In their habits, and choice of food, they are not as delicate as other sheep, thriving and fattening on the most scanty and inferior keep. There is a briskness in their countenance and action, which, to every beholder, bespeaks for them at once their superior constitution. They must be seen to be duly appreciated. Six wethers and one buck, two years old, of my own raising, and two full blooded imported Lincoln bucks, one four and the other three, weigh together 1798 lbs."—an average of about 200 lbs. each.

Early Variety of corn.—H. C. Tainter, of Hampton, Con. wishes to advertise the public, through the Cultivator, of an early variety of corn, called the Clark corn, which was ripe the 24th August, ten or fifteen days earlier, he says, than the Dutton corn he planted along side of it, and he thinks the Clark corn the most prolific. We doubt not the Clark corn is early and prolific; but we will add, in defence of our favorite, the Dutton, that our crop was all fit to harvest in August, and that for product, when well fed, we challenge a competition with any variety. We have cultivated it eighteen years, and never had it injured by frost. *Our* kind of Dutton corn was *harvested* by T. G. Mather, Esq. of Middletown, Con. and his neighbors, in August.

Melon Seeds—We have received seeds of *the* 55 lbs. muskmelon, from an unknown friend at Charleston, S. C.

Berkshire Pigs.—Mess. Brintnalls, of Canterbury, Orange, who have a stock of these pigs, from original importation, cite the following as the weights to which they have attained, at the ages noted: one under two years old, weighed 652 lbs.; one four years old, 702 lbs.; one three years old 780 lbs.; two eighteen months old, 432, and 432½ lbs. &c.

The Grain Worm and late sowing Spring Wheat.—We have received communications from M. M. Wake, and others, which concur in stating, that the spring wheat sown in April and the early part of May, has been seriously injured by the grain worm, in the infected districts; while that sown after the 15th and 20th May has escaped with partial or no injury. Mr. Hill, eighty miles north of Albany, sowed on the 25th April, and again on the 19th and 25th May. The first was a total loss, the second was but partially injured, while that sown on the 25th May wholly escaped the worm. It gives us pleasure to say, that in the northern part of Vermont, where this insect first appeared, ten or twelve years ago, the culture of wheat is being again resumed, with flattering prospects of escaping the ravages of the worm. By the way, the opinion has been advanced by naturalists, that the grain worm is not oviperous, laying its eggs, but viviparous, like the honey bee, bumblebee, &c. depositing its young. Mr. Henry Ellsworth, of Ketch Mills, Ct. has addressed us ten queries in relation to this insect, all of which have been anticipated, so far as we are at present able to answer them, in the Cultivators which we forwarded to him on the receipt of his letter.

A new Insect Enemy to the Wheat Crop, we are sorry to learn, has this year appeared in several districts, and done serious injury. It is represented to be a species of worm, about three-eighths of an inch long, and preys upon the matured grain, in the field and in the barn. As we have not seen the insect, we will be obliged for a description of it, and of its habits, from any gentlemen who has made it the subject of his observation.

Thrashing Machines and Horse-Powers.—We have half a dozen letters of inquiry before us relative to these We have said all we have felt justified in saying of those we have seen on trial. For these opinions we must refer to the Cultivator, and also for the address of those who vend them, the price, &c.

Bog Ashes, &c.—Charles H. Welling, of Lawrenceville, will find answers to his queries in regard to bog ashes, at pages 157, 174 and 190, of our fourth volume

CORRESPONDENCE.

The Lombardy Poplar.

Baltimore Co. Md. Aug. 15, 1838.

J. Buel—Dear Sir—This tree, it appears, has recently sunk very greatly into disrepute, at least in many places, as an ornament and shade in our yards, streets, &c. It is highly probable, however, that the intrinsic excellence of the tree has been but imperfectly ascertained, and known to a very limited extent amongst us. In view of directing more special attention to some of the advantageous uses which may be made of it, I beg leave to communicate the substance of Mr. Baughen's remarks made to me on that subject a few days since.

1st. The Lombardy poplar is a tree of quick and rapid growth,—few more so. 2d. Is adapted to either dry or wet soil. 3d. May be propagated with great ease from cuttings, from the size of a riding switch to that of a large wagon tongue. 4. Sends forth abundance of limbs, which may be amputated without injury to the tree. 5th. Splits kindly even through knots, and when well seasoned makes good fuel; and, in the opinion of some, it is nearly, if not quite equal, to chesnut for rails.

I imagine the tree might be turned to very great advantage by farmers, especially in districts of country where wood is scarce. In a few years whole forests would be produced from cuttings, which could be applied to the foregoing purposes. And let them be planted from 10 to 12 feet apart, where you want permanent fencing, and in a little time you will have substantial posts, into the side of which you may introduce your rail slightly, and one year's growth will bind them tight enough.

I am, dear sir, ELI HENKLE.

NOTE.—The above suggestions address themselves particularly to the prairie west. There is probably no tree which would be made to furnish a forest belt around a prairie farm so soon as the Lombardy poplar, and none, certainly, could be so easily propagated. As a shelter for crops, for farm stock, for a growth of other timber, for fencing and for fuel, it would soon become highly valuable. Cuttings almost enough for a forest, might be transported in a dearborn, or one-horse wagon.—*Con. Cult.*

Millers' Tolls—Crops.

Burlington Co. N. J. 8 mo. 27th, 1838.

FRIEND BUEL—I perceive in the last number of the Cultivator, that a correspondent over the signature of William A. Stone, accuses me, with a certain John Westley Luff, of justifying millers in taking extortionate toll, which, on my part, I deny being the fact; nor would I, upon any consideration, support them in taking more than one-tenth by *measurement;* neither can he thus make it appear, unless he can show where you have stated that they have taken more than the above proportion in like manner ascertained. And as I apprehend my premises have not been clearly comprehensible to his understanding, I will endeavor to state them as explicit as possible, viz. that the tenth, as above determined, with what millers in this district of country extract in the process of cleaning, (and that too without the waste of grain, as will be shown to your correspondent, or any other person at any time,) would, with the escape of fixed air, amount to more than the tenth-part of the original *weight* of the grain when taken to mill; and until he proves that there is no unavoidable diminution of weight in the grinding of grain, or that it can be attributed to some other cause more certain than the departure of fixed air, the which he has not even attempted to do, my statements remain sound and unrefuted.

And in reference to G. W. Luff, he says, "that if he gets more loose air, (I suppose he means atmospheric air, and presume the term to be his own, as it is not marked as a quotation, nor can I find it used in Blair's pneumatics,) in any species of grain than its circumference will contain, he will have to employ some artificial power to aid nature in her wonderful and mysterious works of its germination," thus substituting his own for the philosophy of Martin, who expressly says, "that this fixed air as it is roused, expands itself into about a million times more space than if filled before in the form of a dense body;" or in other words, in the position in which nature placed it "in her wonderful and mysterious works" of formation, and whose philosophy is as worthy of credence as the Rev. Dr. Blair's. And whereas, your correspondent appears better versed in the science of weighing air, according to the standard of Blair, than in correcting insinuated false principles, I will leave him to calculate what his wheat will lose by *fixed* air, for I do not comprehend by his communication, what atmospheric or loose air has to do with the just or unjust tolling of grain; and I will also just inform him, through your columns, that if he will favor me with the grinding of some of his wheat, I will toll it both *scientifically* and lawfully, as nearly as I am capable of regarding the weight after manufacturing.

Respectfully, DAVID WALTON.

P. S. We are extremely parched up by the drought; our corn in very many places nearly killed, and what little there is will soon require husking. There is no appearance of any buckwheat worth naming, neither can we prepare our ground for sowing wheat. Our pastures are assuming the appearance of winter, and what little there is of green herbage the grasshoppers destroy, and some fields of corn are considerably injured by them; they far exceed in number any thing of the kind we ever saw. Some farmers are, and have been for some time, feeding their cattle, and report says, cows may be obtained in the Philadelphia market for ten dollars per head. We had an abundant crop of grass, and an excellent time to gather it, or we should indeed be in a deplorable condition for our stock, as our ruta baga and beets are also very far short of an average crop. Hay, which in Philadelphia market but a short time since, would not bring more than fifty or sixty cents per cwt. will now command from eighty cents to one dollar. We have had no rain of any considerable consequence, for about two months. We have had one or two very trifling showers during the time, that seemed to revive vegetation for a day or two, and then it would again languish as before. D. W.

☞ The vexed question, as to the loss of a bushel of clean grain in grinding, might be easily settled by experiment.—Will some gentleman *see* a bushel ground, weighing it before and after grinding, and send us the result?—*Cond. Cult.*

Tolls Again.

Moorstown, Aug. 8, *mo.* 16, 1838.

FRIEND BUEL—The communication of William A. Stone, by way of refutation to an article under the head, "Miller's Tolls," in the May number of the Genesee Farmer, and June number of the Cultivator, I consider not quite correct, or at least not strictly adapted to that article. If he is dissatisfied with their deduction for toll, or standard of tolls, I conceive him perfectly right in communicating the censure. But, with all respect, I must tell him, in rejoiner to the individuals, (D. Walton and J. W. Luff,) he has fallen into an egregious blunder, by asserting that 60 lbs. of wheat contain no more than one bushel of loose (denominated fixed) air; and which, he says, cannot be proved by practical philosophy. And, says the writer, I further contend, that if these gentlemen get more loose air in any species of grain than its circumference will contain, he will be obliged to employ some artificial power to aid nature in her wonderful and mysterious works of its germination. Here I dissent with the writer, and cannot reconcile it with principles of the philosophy he has quoted. Blair, the author he cites, only says, 1,000 cubic inches of air weigh 324 grains, and it is 900 times lighter than water. The weight of the air being variable, a great number of experiments have been made by different individuals, with as many different results, but the above would probably represent nearly the mean.

Now it is a determinate truth in philosophy, that solid bodies contain a certain quantity of air in a solid or fixed state, which quantity differs in different species of matter; hence it becomes a consequent truth that this air constitutes a proportional part of their weight; and, according to Oliver Evans' observation is variable in different species of wheat, from 4 lbs. to 12 lbs. in 60 lbs. or one bushel of wheat. Again we have from the experiment of David Walton, a practical miller, the loss of weight in grinding rye, to be 3½ lbs. per 56 lbs. or 1-16 of the quantity ground. Can we, without a knowledge of the composition, analysis, and organic action of vegetable substances, conceive that this quantity of air exists in one bushel of wheat or rye, other than in a solid or condensed state, greatly exceeding its original density? Hence it appears evident, that the degree of heat generated by grinding with great pressure, disengages this fixed air, and causes it to leave the flour, thus greatly lessening its weight.—Now if the statements of these practical men give the true aggregate amount of loss in weight during the process of grinding, I think it cannot be accounted for any way better than supposing the loss produced by the escape of the fixed air. Yet I admit no treatise on philosophy is better established than that quoted by our friend from Rahway, but unfortunately, where he would wish to apply it, it has no application. Now, if he will brush up his ideas a little, he will discover that his philosophy and Oliver Evans' sustain little or no relation to each other.—The mere circumstance that the Rev. David Blair says, a bushel measure, or 2,150 2-5 cubic inches of air, will weigh a little more than 1 oz. 9 dwt. is no proof that one bushel of wheat does not contain fixed or condensed air.

These extortionate tolls (as he calls them,) may be a subject of controversy with the miller and the farmer, which I wish not to engage in, by bringing into requisition an unnecessary multitude of words; much less do I intend to dispute with our agricultural friend. He may tell us of our faults freely, but we will be careful not to see any of his if there should any exist. Most respectfully, thy friend,

SILAS WALTON.

Hard Times.

J. BUEL, Esq.—I have a number of periodical visitors, with whom I like to hold sweet converse; and no one whose return is anticipated with more pleasure than Mr. *Cultivator* from *Albany*. He is punctual, desirous of communicating all that is useful; and above all, frequently tells me what my neighbors say. When I last saw him he presented to my view the thoughts of "An Agriculturist" on "The Times," a title so full of meaning that my attention was more than once directed to the subject. I fully agree with the writer, that the *times* have not so much affected the *farmer* "as other causes." I would commend his views on extravagance, improvement of the mind, &c. to all with whom my visitor comes in contact.

It is fashionable, in some places, with agriculturists, to pursue just the same course that has been pursued the last half century; and if perchance any one deviates from the old trodden path, by way of experiment, the "cruel fashion" makes him a subject of ridicule, and damps the ardour of others, who might otherwise be inclined to think and act for themselves. Could not then "this trouble" be avoided by the "tillers of the soil," if they were not "under the dominion of this *hydra fashion*?" I hope to hear again from "an agriculturist" in reference to his crops, mode of ploughing, &c. and indeed anything that his experience may suggest on the important subject of agriculture.

I believe the *stigma* of being a "*book farmer*," has shut the doors of many in this vicinity, against the visits of the Cultivator, and other kindred works; but light is dawning, and as it increases, *hard times* with the agriculturist will decrease. W.

Westborough, Mass. Aug. 27, 1838.

Blight—Crops, &c.

Newark, Aug. 15, 1838.

DEAR SIR—I have long been making observations upon the fire blight in trees; and although the public has been much bored by ridiculous theories, and mine may be as much so as any one, I will venture to lay it before the public, through the medium of the Cultivator. To entitle a theory to the attentive consideration of the public, it should be based upon facts sufficiently numerous and varied, to make it plausible. To give all the facts upon which I have founded mine, would require more than the space of a single letter. But I may give sufficient to call the attention of pomologists and horticulturists to the subject.

I impute this singular effect to the aphis, and I think its ravages are by no means confined to fruit trees, and that other shrubs and trees infected with these vermin, are victims of its influence, in a greater or less degree. The monthly roses in my green house, small shrubs in my garden, my quinces, paradise apples, as well as pears and common apples, are subject to the blight; and I have not yet noticed an instance of blight upon any tree that was not very much infested with aphides in the months of May and June. So satisfied was I upon this subject, that in those months I visited several gardens and orchards, and pointed out to those in company with me, trees that would be blighted, distinguishing those that would be slightly from those that would be severely affected. The event has justified my predictions in every instance. A seckle pear, of a friend of mine, has suffered much from this cause, in the three past years. I found not an aphis upon it this year, and there is nothing like blight upon it up to this time. This tree may die from a disease which is preying upon its root, but its top is yet vigorous and full of fruit. Now the question arises, how can this insect produce this effect? In various ways. By its minute puncture it may destroy the vessels of the tree and leaves, its excrement may form a varnish impermeable to the air, and thus destroy the absorption and exhalation of the part; or it may be poisonious, when taken into the circulation of the juices. Referring this disease to such a cause, will account, in some degree, why it is not constant. We well know that the prevalence of insects is variable. Some years more and some less, or for a series of years more and again less.

One other fact I will mention. I have an apple tree that has in years past been severely injured by the blight, which stands within a few feet of the flue of my green-house. Last spring, when the buds were swelling, they were covered and black with the aphis. When the wind was in the right direction, I threw tobacco stems and leaves into the stove of my green-house, and the smoke passing through the tree soon caused them all to disappear Not a leaf or limb is touched with the blight this year.

The present has been a most remarkable year for vermin of every kind. Striped squirrels, birds, caterpillers of every known and many unknown kinds, worms and bugs, have infested plants and herbage of almost every description. The curculio has been very abundant. I have lost all my plumbs, notwithstanding I killed hundreds of them. Do you know of any preventive to their ravages? How would it do to sprinkle salt, ashes or lime around the roots of the trees, to destroy their larva?

The extreme heat of July will very much injure our late crops. The moisture was literally baked out of the earth. Corn crops must be light.

A friend the other day brought me the branch of an apple tree, on which there were two very large cocoons, and a green worm about five inches long, three-quarters of an inch diameter, just commencing his cocoon. Such mammoth silk-worms must be great feeders as well as great producers.

ISRAEL DILLE.

Remarks.—We either misunderstand what our highly respectable correspondent terms blight, or we are obliged to dissent from his opinions as to the causes which produce it. That the aphides, and all other parasites, animal or vegetable, which abound upon plants, are prejudicial to their health, and often destroy them, is a position not at all doubted—for these parasites subsist on the juices, or sap, which is destined to nourish the plant; and the injury is in proportion to the quantity of sap which is abstracted. But what is termed blight in the pear, and often in the apple, and other trees of the Pyrus family, cannot, we think, be caused by an aphis, for this insect seems ever to be with us, while the blight of the pear often intermits for years.

Substitute for Spaying.

Ivanhoe, Campbell Co. Aug. 18, 1838.

Dear Sir—I have been for some time an attentive reader of your valuable paper; from each page information is to be gained. In your last number, you instruct us how to perform the operation of caponing cocks, before which I knew not. And it is the above which prompts me to give you the following information:

The old method of gelding sows is not only very cruel, but quite disagreeable to the operator, as well as dangerous to fat animals. Now sir, the modus operandi in this neighborhood, as practised by myself lately, but much longer by others, is simply this: For convenience use a common goose quill as a tube, cutting off smoothly the small end, the other shaped as for a tooth-pick, to be used as a handle; then pass the small end down the vagina two inches or more, (according to the size of the animal,) through which drop six or seven shot, say No. 3, and your work is complete. Nothing can be more simple, innocent, or efficacious.

Should you think the above worth making known, you can publish it. Very respectfully, your ob't serv't. EDWARD B. WITHERS.

Modes and Profits of Strawberry Culture.

Narrows, L. I. Aug. 15, 1838.

Mr. Buel—Having noticed an article in your August number, on the cultivation of strawberries, to which my attention has been directed for a number of years, and wishing that the public should receive all the light upon the subject which can be diffused, induces me to communicate what little knowledge I possess of the matter. The kind generally cultivated on Long-Island (where I reside) for the supply of the New-York market, I believe to be the early scarlet, and of these I have at present about three acres under cultivation. We generally transplant, and form our new beds in the beginning of May. Formerly the universal practice was, to transplant in rows from two to two and a half feet apart, the plants single from one to one and a half feet from each other in the rows. My present practice, and that of many others, is to plant them in hills about three and a half or four feet asunder each way, placing four plants in a hill, two and two together, about three inches apart. By planting in hills there is a great saving of labor, for it takes less time in transplanting, they are more easily kept clean by running the cultivator through them both ways, and there is less labor in hoeing; whereas, by the old method, when planted close, the cultivator could not be used in them at all, or at most only one way. The cultivator is run through them as late as it can be done without serious injury to the runners, hoeing them each time, and it is seldom, when judiciously done, they require it over three times. I have always, in my practice, found them when properly managed, to cover the ground with a sufficient number of plants to produce a good crop of fruit the next season. A piece covering less than a half acre, of last year's planting, produced this season over 3,000 baskets, containing nearly a pint each, which were sold in the New-York markets for $200. This, however, is an uncommon yield, and is seldom equalled or excelled. New beds almost invariably yield better than old ones, and produce larger fruit, although apt to be sandy after showers. It took nearly two acres of my old beds to yield the same quantity the half acre of new did. The soil I prefer for strawberries, is light sandy land newly cleared, on which no animal or vegetable manure has been used. On land of this kind, which has been prepared by previous crops, and on which weeds have not been suffered to go to seed and take possession, they will last four or five years, while on old land they are seldom profitable over two, and often but one.

The greatest enemy to the beds is white clover, which, in old lands, after the first year's bearing, generally gets possession of the beds and eradicates the plants. Land lately cleared is not often troubled with this grass; the great danger is from sorrel, but this is less destructive. Our beds cover the whole ground; there are no alleys, no clipping of runners, no digging the paths, no burning with straw, as recommended by some gardeners, for it is doubtful whether these operations would answer our purpose, whether they would be profitable and pay cost. At all events, our experience leads us to adopt the plan I have described. The only attention which I have found necessary and advantageous after the first year, is to pull up and destroy the weeds and grass, and to run a light harrow over old beds, early in the spring, when matted too thick with plants. As for manure, it is not customary for us to put any on. I once read an account of plaster being highly beneficial, which I tried, but it failed in improving them. Lime might aid in destroying sorrel, but have not tried its virtue.

Much has been written about male and female plants, and of the necessity of mixing them in the beds to make them fruitful. Now all this may be necessary with some varieties, but with the one we cultivate I can assure you it is not; no cultivator in my neighborhood, from which the New-York markets are principally supplied, that I have ever heard of, does it. I once tried an experiment, which appears to me conclusive. I planted a small bed in my garden at the time when the fruit commenced ripening, taking only such plants as had good and fair fruit on them, and no others. This bed produced the next year abundantly; they were all female plants, and no males in their vicinity to impregnate them. The male and female blossoms of this variety must be on the same plant, although to the eye no difference is presented in their appearance.

If you deem these remarks worthy of notice, you may insert them in your valuable journal; and if you desire it, I may at some future period describe the manner in which cucumbers, melons, &c. are cultivated among us for the supply of the New-York markets. Yours, TUNIS G. BERGEN.

We shall be glad to receive the profferred communications. —*Cond.*

Early Varieties of Corn.

Hebron Centre, Aug. 27, 1838.

J. Buel, Esq.—I send you two ears of corn, picked this day from a neighboring field. Both varieties have been cultivated in this town for many years; the twelve rowed has been the most productive, until the two last seasons; the early frosts cut off the most of it before it had ripened. The corn, when ripe, is very hard, and weighs three or four pounds in the bushel more than the common flint corn; it is very compact on the cob, hard, and when ground produces the finest meal; it may be called the Rhode Island flint.

The eight rowed is a fine variety; planted in the same field, on the same day, and manured and managed in the same manner, ripened eight or ten days earlier than the Dutton corn, and now promises a production of twelve or fifteen per cent more. There are now standing several hills (planted for an experiment,) of this year's growth, without more than ordinary care, that are six inches high. Will you be pleased to give the three varieties a fair trial, and in due time report the result in your very useful periodical publication? My only object in making this communication, is to give the greatest reward to the laborer who cultivates the ground, and best obeys the command of God given to our first parents—go "*dress the garden.*" Could our citizens be induced to return to their primeval innocence and simplicity, the whole earth would become an Eden. With great respect,

J. S. PETERS.

☞ The samples noticed above, have been received.—They are, as represented, beautiful samples of yellow flint corn, the grain covering about nine inches of the cob. We regret that Gov. Peters did not note the day on which they were planted, as we can only judge of its comparative earliness by knowing this fact. Some of our Dutton variety was planted on the 19th May, and the crop harvested on the 22d Aug. being 93 days. In Maryland, and elsewhere, it has matured in less than 90 days.—*Cond. Cult.*

Culture of the Strawberry.

Loretto, Va. Aug. 18, 1838.

J. Buel, Esq.—Dear Sir—The perusal of your interesting article on strawberries, induces me to offer my testimony in confirmation of some of the facts and opinions therein stated. Not that I can suppose any of your readers would desire better authority than your own; but because the value of all statements whatever, as to practical matters, will always be increased in proportion to the number of credible experimenters who testify in support of them.

The burning of strawberry beds is a very old practice. I myself have known it for nearly, or quite half, a century; have often seen it tried; and with such invariable success, that it is surprising it should not be general. But it must be done immediately after the vines make their first appearance in the spring, and no more straw should be used than sufficient for spreading the flame equally over all the plants. This process not only benefits the soil in some degree, and kills the seed of weeds scattered on the surface, but it retards the bloom, and thereby often saves the fruit from destructive frosts. It also secures a succession of fruit, which is better than cultivating an inferior kind for the purpose.

I can likewise vouch, from long experience, at least in regard to the claret-coloured hautboy, that, if you would have any fruit, you must plant male among female vines. This is the only variety known to me, which leaves the male and female blossoms on different plants; although others may do so, but I have never noticed it. As to the best proportion of male to female plants, I cannot speak with certainty, having tried only that of one male to 12 or 14 females. By the way, can you inform us *what are* the distinctive characteristics of the hautboy, and what the derivation of the name?[*] I know of only the following peculiarities, viz. leaves of a yellower green, with a rougher and more corrugated upper surface, than any other variety; fruit of a spicy flavor, a very fragrant smell, and scarcely any perceptible acid in the taste. The claret coloured and white are the only hautboys I have ever seen that answer this description. All the other kinds known to me, amounting to six or seven, have leaves of a deeper green, and smooth on the upper side; while the fruit, however variant in taste, is much more acid than the hautboys, has quite a different odour, and is invariably of a red colour, although exhibiting various shades of scarlet and crimson. In some of our Virginia gardens, one of our wild varieties has been introduced, which has this peculiarity: in pulling the berries, when ripe, they separate entirely from the stem, which saves the subsequent picking, which must be performed on all the others. In flavor none are generally deemed better, except the old fashioned, round, scarlet kind, which was almost the only kind cultivated in "the ancient dominion," forty or fifty years ago, and which may claim a preference, by prescriptive right, over all others—even in opposition to the long established *dictim*—"De gustibus nil disputandum."

Among the varieties mentioned by yourself, you speak of "*the Methven;*" and you say—"you had many that measured over four, and one that measured five and one-quarter inches in diameter." Is not the word *diameter*, in the foregoing sentence, a typographical error?[†]

As to the culture of this delicious and wholesome fruit, I can only say, that *some* is indispensable to the production of the best and greatest quantity, be the variety what it may. The "let alone" system, so fatally pursued by congress and our state legislatures in general, towards agriculture, which may truly be called the life-blood of every trade, profession and calling in society, is equally fatal to—*strawberries*, (if small things may be compared to great;) they *must* have some culture, or they can never be brought to their highest state of perfection. But in regard to this, each pursues his own fancy, for the fact is, that we have scarcely any thing among us which has the slightest pretension to be called *system*, either in gardening or general agriculture; our sons having been usually brought up to entertain a most ineffable contempt for that great bug-bear, *book farming*, which, of course, comprehends gardening amongst the things not to be taught by books. The fatuity on this subject may be reduced to a sort of syllogism, thus:

Our fathers and great-great-gandfathers farmed and gardened pretty well without books.

But we, their sons, and great-grandsons, are ten times as wise and clever as they were;

Ergo, we are amply qualified to farm and garden it too, ten times better than they could,—unaided *by*, and independent *of*, any and every thing that bears even the semblance of a book.

But thanks be to you, sir, and to all your able brother editors of agricultural papers, for the zealous, constant and judicious efforts which you and they are now making, in every part of the country, to awaken the Rip Van Winkle's of our class, from their long and deadly sleep. The fatuity I have just stated, cannot last many years more, against such efforts to remove it; and that you may all live to see your most sanguine anticipations accomplished, in this respect, is the sincere wish of, dear sir, yours, very respectfully,

---

[*] The distinctive botanical character of the hautboy is—"Calix of fruit reflexed, [no other species possessing this character but the wood strawberry,] pubescence of peduncles and petioles much spreading." The specific name *hautboy* (elatior in botany) is supposed to be derived from its *high* growing habit. The hautboy is often termed the *musky* strawberry, from its musky fragrance.—*Cond.*

[†] This was an accidental error in the manuscript. It should have read "circumference," instead of diameter.

JAMES M. GARNETT.

P. S. There is a means of distinguishing the male from the female plants of the hautboy, besides that by the blossom; but I have forgotten it. Can you inform us what it is?

The Vermont Bee-Hive.

Hon. Jesse Buel—Sir—In my communication, which appeared in the Cultivator, May last, relating to the construction of a *bee-house* and *bee management*, I recommended my mode of growing honey, in preference to the old mode of managing bees, where it was designed to facilitate their cultivation among those who would pay but little attention to them, dislike the task of hiving, and render them more safe from the destruction of the moth and other casualties, than the ordinary method by which bees are generally kept.

In all cases where it is convenient and desirable to the owners of bees to devote their attention, hive them where they swarm, and those who wish to realize a profit from this insect, by forwarding yearly a quantity of honey to market, I do freely, and consider it no more than justice due my neighbor, Mr. John M. Weeks, and the community at large, recommend the Vermont bee-hive, which is considered the best in use by a majority of the apiarians of this state, and is coming into general use in most of the states in the Union.

This *hive* was invented and patented by John M. Weeks, Esq. of Salisbury, Vermont, who has from youth devoted a portion of his time in studying their nature, and most assiduously for the last eight or ten years, in observing their habits and demonstrating facts; the result of which no doubt is opening a new era in bee management, from which the public must derive a great benefit.

He is considered the first apiarian in this state, and it is a matter of doubt whether there is one in these United States that has investigated the subject, and made so many discoveries respecting the nature and habits of this instructive little insect, as Mr. Weeks, who has been at several thousand dollars expense, in time, in experimenting, publishing books, illustrating facts, &c. &c.

When on a visit at his residence, a few weeks since, I could not but feel deeply interested in his illustration of facts, as exhibited to us by means of *full observing hives*, (glass, covered with wood,) neat and elegant as any parlor furniture; the chambers filled with the most pleasing and admirably constructed drawers of glass, and drawers filled and filling with beautiful honey, without bread, or any thing unpleasant in its appearance. These drawers are taken out and sent to market at any season of the year. He informed us that he usually obtained from his old stocks, from twenty to thirty pounds of honey in these drawers annually, and from his earliest young swarms, thirty pounds and over, without robbing them of their winter stores. The Vermont hive affords an easy and safe method of preserving the lives of the bees through the winter, without destroying any. He showed us a *feeder*, and the manner of using it. Through the means of this, the bees may be fed on low priced or sale honey. We noticed several healthy stocks, which he informed us were wintered entirely on Havana honey, and have yielded several boxes of clover honey this summer. We were also informed that the principal part of bee management depends on a knowledge of the natural habits of the queen and her influence; and no apiarian can at all times be sure to succeed in their cultivation, unless he has a thorough knowledge in managing them.

He also instructed us in his art of compelling the bees to make and keep on hand extra queens; how they may be divided into separate colonies when they have become too numerous, without swarming.

He showed us how the bees would transfer themselves when the age of their combs rendered it necessary, by a little aid of their owner, and urges, by many arguments, that bees should never be compelled to leave one tenement and take another.

We observed in one hive, that he had killed the queen and confined her therein. In this experiment, Mr. Weeks is about to demonstrate several important facts, viz: That there is no monarchical government in a hive of bees, nor domineering power in a queen; though the queen may be dead the bees will continue to work as well, provided her carcass be present; and that no young bees can be raised without a queen; the old bees never eat bread, &c. These experiments Mr. Weeks intends to publish, and their results; therefore I can only say, that it is an interesting system, which affords an agreeable amusement, a comfort and profit. He advances his opinion, that bees are susceptible of a high state of cultivation; that they will never flee to the woods and mountains, unless neglected by their owner, or through a deficiency in knowing how they must be managed; and that he had not lost a swarm by flight to the woods in seventeen years. One reason of the bees deserting for better quarters is, when the rays of the sun are direct it exhausts the air in the hive of its vitality. Mr. W. sells the common coarse wood drawers of honey, in Boston, at from thirty-four to forty-two cents per pound, by the quantity; and for his best glass and mahogany boxes, he receives a higher price.

Mr. Aaron Barns, of Rutland, states, that ten of his swarms in the Vermont hive, produced, last season, $75 worth of extra honey.

Mr. Week's last edition of books on the management of bees, have all been ordered, but another edition will probably be published the ensuing winter. He is ever ready to congratulate all those who may call on him—such as parties of pleasure, amusement, and profit, and none can leave without a taste of his bread and choice honey; in addition to a pleasing course of lectures on the natures and habits of the honey bee, and other insects, which are very entertaing, instructive and useful. Respectfully yours, SOLOMON W. JEWETT.

Weybridge, Vt. August, 1838.

Patronage to Agriculture.

Goshen, Aug. 27, 1338.

Jesse Buel, Esq.—Dear Sir—If you think the following will subserve the cause of agriculture, you can give it a place in your valuable journal. It has always seemed surprising to me, that this country, which is so productive in the fruits of the earth, should have received in its agricultural department so little aid from its rulers. While patronage is extended with a liberal hand to the various mechanical arts, and improvements in machinery anxiously sought after, the parent art, upon which all others depend for their support, is neglected. I know that the fault, in some measure, rests upon the people themselves; but something should be done to elevate the standard of agriculture. The ancients took much more interest in the cultivation of the soil, than is manifested at the present time. The arts and manufactures had not attained their present state of perfection, and it was only by the tilling of the soil that the greater portion of the inhabitants were enabled to procure a subsistence. But their kings and princes, orators and great men, united in carrying the science to such a pitch of perfection as has not been seen since. A great many excellent treatises were composed upon the subject of which we ought much to regret the loss. The kings of Egypt were famous for their skill in husbandry, and for the improvement they caused to be made in that country. They caused drains to be made to convey the water of the Nile to the dry and arid tracts not usually irrigated in the annual overflow of that river. Of such utility were these improvements, combined with the fertilizing properties of the water brought from the Nile, that the country of Egypt, consisting of only 6,000 square miles, comprised, as we are told by Pliny, a population of 20,000,000 souls. This amazing fertility, although caused principally by the Nile, could not have benefitted the Egyptians in a very great degree, without the kindly aid and instruction of their rulers. Cicero, also, one of the first orators of Rome, devoted much of his time to agricultural pursuits. He composed many valuable works. Virgil also has immortalized himself in his Bucolics. But perhaps of all the kings recorded in history, Hiero, king of Syracuse, in Sicily, stands first as a patron of husbandry. He came in possession of the throne at the age of thirty, and found the country convulsed with seditions and corrupted by luxury. He soon succeeded in placing agriculture in honor among his subjects, who, whether high or low, rich or poor, applied themselves diligently to cultivating the soil. The consequence was, that in a few years the inhabitants of Sicily, a small speck in the Mediteranean, who were in the habit of importing nearly all their grain from the continent, had now a large surplus for exportation. This brought the wealth of the surrounding country into their own, and then into the pockets of the farmers. By means of these wise regulations, he also kept an infinite number of hands busy, which might otherwise have been employed to the detriment of the state. This is a policy which should (and it cannot be too often repeated) be the peculiar care of a wise and prudent government, but it is often sadly neglected. Hiero's laws were so excellent in this respect, as well as others, that sometime afterwards, when the island became a Roman province, the inhabitants were allowed to be governed by their own laws, the Romans not being able to substitute any thing better in their room.

And why, permit me to ask, may not the example of Hiero be imitated in this country? It is from the legislatures of the several states that we must look for encouragement, in a government constituted as ours is. They have begun to awake, and have done something, as is the case in regard to Maine, Massachusetts, Kentucky and Pennsylvania. But much still remains to be done.

The condition of agriculture at present, is somewhat analagous to that of our common schools.—Something should be done to give the useful science of agriculture its proper respect in the minds of men. Education and agriculture should go hand in hand. All improvements in the one should be met by improvements in the other. The power and influence of the general assembly, are acknowledged by many to be necessary in advancing the character and promoting the usefulness of common schools—Why should not that power and influence be exerted in forwarding the usefulness of agriculture, upon which so much depends, and in which so many are concerned? That august assembly, the senate of Rome, did not think it beneath them to bring this art to perfection, and why should the legislature of this country neglect so important a source of revenue? In the hope, dear sir, that this may not be altogether out of place, I remain your obedient servant. CHARLES STRONG.

Bone Dust.

New-York, Aug. 20, 1838.

In your number for August, you gave an article from the Aberdeen Journal, on the operation of bone dust.

The writer states, that "bones are phosphate of lime—that is, they are composed chiefly of lime and phosphoric acid." So far the writer is correct, but he goes on to theorize on the effect produced when crushed bones are mixed up with soil as manure, and here his theory is at variance with practical facts. He says, "When crushed bones are deposited in the earth, by the action of heat and moisture, the bones are soon reduced to a state of decomposition, and the original elements of which they are composed are thereby set at liberty to form new combinations in the great circle of revolving nature." He then goes on to say, that "the lime is left in its caustic state, deprived of its neutralizing acid; and the phosphoric acid is set free in the form of gas."

It is exceedingly easy for any flippant writer to produce a plausible theory; but when chemical action forms the foundation of a theory, the writer should be sure that the agents he employs are equal to produce the effects he ascribes to them, or his theory decomposes itself.

There are few materials more difficult to decompose than bones, or phosphate of lime. To decompose bones, they are first calcined, then ground to a powder, and are then mixed with forty per cent of sulphuric acid, in which state they remain for two days, being frequently stirred. The solution is then poured on a filter, and the liquor passing through is added to a solution of nitrate of lead—the white powder which forms is mixed with char coal powder, and has then to be exposed to a strong red heat in a porcelain retort, when the phosphorus distils over.

The affinity of phosphoric acid for lime, and the affinity of lime for phosphoric acid, is so great that none of the alkalies will take the phosphoric acid from the lime, and none but the most powerful acid will take the lime from the phosphoric acid. After all it requires several hundred degrees of heat to liberate the phosphorus.

In the process I have described for obtaining the phosphorus, the sulphuric acid combines with the lime, forming a sulphate of lime, and the phosphoric acid is liberated. I would ask the writer of Aberdeen, what acid there is in any soil sufficiently powerful to decompose phosphate of lime, and if the lime could exist in a caustic state after coming in competition with an acid sufficiently powerful to decompose the bones?

The probability is, that bones act merely as phosphate of lime, and that the only change which takes place when used as manure, is the rendering the particles so fine as to be held in solution by moisture, and in that state are taken up by the absorbent vessels of the plant. WM. PARTRIDGE.

J. Buel, Esq.

Novel Premiums.

Lake C. H. Ia. Aug. 27, 1838.

J. Buel, Esq.—Dear Sir—Not being blest with an overplus of gold and silver, I propose to offer a "barter trade," to any one desirous of obtaining a premium, upon the following proposition: I am the owner of sixteen lots, in one of the numerous new towns of the west. It was laid out in 1836, about three miles from the head of Lake Michigan, on the great western thoroughfare which passes the head of the lake, between Chicago and Michigan city.—About $20,000 worth of lots were sold at the first sale, at prices higher than they now are worth.—Yet I find from the assessment roll of 1838, now on file in my office, that the average assessed value of my lots, is $55 each. The Buffalo and Mississippi rail-road, and a branch from the Lake Erie and Michigan canal to the Illinois canal, have been surveyed through the place, so that property is more likely to rise than fall. However, such as it is, I freely give, and if worthily won, I hope it may rise in value as fast as similar property has done all over the great west.

So, then, to the offer. I appreciate your remarks in the Cultivator, No. 6, on the great want of "Agricultural School Books." Now to induce some one to begin a series of such elementary works, that will have a tendency to learn American youth such things as are the most important of all things for them to learn, that is, how to support themselves and families by the labor of their own hands, I offer, as a premium, five of the above mentioned lots, to any person or persons who will publish a series of five numbers of an "Agricultural School Library," to be submitted to, and approved by you, or any other gentlemen that you may associate with you for that purpose.

And I will also give two of said lots, to any person that will publish another work, to be called, and to be what it is called, "The Farmers' Manual," to be also submitted to, and approved by you, and to contain such maxims and advice as will be useful to new beginners in agriculture, whether old or young; rules that will be useful to the wife as well as husband of such as are driven by necessity or choice from the employment in which they may have always been engaged, to take up the, to them, new employment of cultivation.

Thousands are deterred from attempting to earn their own living, because they *don't know how to begin.* Such would rejoice to have it in their power to procure such a book, as much as a navigator upon a strange coast would rejoice in procuring a new chart.

And in addition to the premium, I will subscribe for ten copies of each work, and take the agency of selling them without commission. Will some one, more able than I am, add to the premium.

And I will also give further premiums, to other objects that you will point out as worthy, which will tend towards the same object. That is, the promotion of agricultural education; for I am convinced that the great object in view must be accomplished upon the rising generation.

A thought strikes me of another work worthy of "a premium lot,"—an Agricultural Dictionary; to be used not only as a necessary accompaniament to the series of school-books, but as an invaluable work in the hands of every cultivator. I venture to say, that there are not one half of the readers of the Cultivator, (and no paper uses less unintelligable phrases,) who are not often puzzled to give the proper signification to necessarily common words.—And to youth, the common names of soils, earths, and parts of plants, &c. are all Greek. To prove it, select fifty words that are found in every agricultural work, such as argillaceous, silicious, phosphate, sulphate, hydrate, carbonaceous, stamens, stolens, et cetera, (including the "et cetera,") and ask fifty of the first persons that you meet, to give you an intelligible definition of them, and see whether the answers do not demonstrate a very great necessity for our agricultural dictionary. If the publication of one cannot be induced, let me ask whether a page of your paper might not be profitably devoted to that purpose. It is a great fault in all education, that we teach words without conveying any definite idea of their meaning.

One of the great benefits which I hope to live to see grow out of the formation of "the American Society for Agriculture," is an improved system of education throughout the whole country. I commend to your particular notice an article in No. 51, of the Franklin Farmer, upon "Agricultural Education."

What think you of a universal petition from all the friends of agricultural improvement and education in the U. S. to the next congress, for the establishment of a national agricultural school? Are we so much more of a warlike than an agricultural nation, that we endow a "military school," to the entire neglect of an agricultural one. Here, certainly is something wrong. "Something must be done,"—who will say, "something SHALL be done," and make the first step towards it by printing and sending a petition over the country for that purpose? The little that can be, will continue to be done, by your friend,

SOLON ROBINSON.

REMARKS OF THE CONDUCTOR.

The ardor and zeal displayed by our esteemed correspondent, in his several communications, published in the Cultivator—directed, as they are, to the substantial improvement of the mind and the soil, are worthy of all praise. And he has given above unquestionable evidence of his sincerity, in the liberal offer he makes to subserve these noble ends. The mind must be enlightened before the soil can be improved. To second this generous proposal, we promise to add $20 to each of the six awards proposed in the above communication. How much will you add, philanthropic reader?

Grape Culture.

Brooklyn, September 10, 1838.

Dear Sir—In one of the late numbers of the Cultivator, Col. Spooner, of Hempstead, L. I. has furnished your readers with a detailed statement of the culture of the Isabella grape; and its conversion to wine. He justly remarks, that much is to be learned concerning the culture of the vine; to which I add, that its culture has proved, and will continue to be a most efficient aid to the temperance cause. Such considerations, therefore, must commend it to the attention of every philanthropist, and induce his aid in extending its culture.

The great enemy of the grape is the rose-bug, which appears when the vine is in blossom. The Colonel remarks, "in a few days after their first appearance, thousands are seen carrying destruction through the vineyard." The best remedy he could devise, he adds, "is to go among the vines early in the morning, before the sun has warmed them into activity, and they are then easily destroyed. A few mornings spent in this way, will clear the vineyard, as they are a short lived enemy."—The Colonel is fortunate, if his destructive visitors leave him in a few mornings; with us, in Kings county, they protract their visit for *weeks*.

Rose-bugs, in my neighborhood, have, in some places, entirely destroyed the crop, both this and the last season; while my grapes, which were nearly surrounded with *rose bushes*, escaped their ravages. It has been the practice of many, to remove rose bushes to a distance from the grape vine, but without success. The cause is evident, they attract the bugs, but they serve also as a trap to secure them. The Colonel's plan is doubtless the best, *when practicable.* He would find it difficult to *catch bugs* on vines trained to a great height, as they generally are in villages, besides, as they can only be caught when the morning dew is upon them, their extermination would require many mornings' labor, and in the mean time the blossom would suffer from their voracity. Col. Spooner's communication will, however, prove extremely valuable in villages and cities, by furnishing the mode of trimming the vine to thousands, who never would consult a regular treatise upon the subject, but would suffer the impositions of gardeners, who, by making a great mystery of the manner of trimming, contrive to extort large sums for a very trifling labor. And, en passant, I may add, that article alone is worth double the yearly subscription price of the Cultivator. The Colonel requests of your correspondents, information in relation to the culture of the vine, and inquires whether manuring is desirable? What kinds? and to what extent? &c. &c. His valuable article entitles him to any information on the subject your correspondents can afford; and I trust it will receive the attention it merits.

My experience has been too limited to afford full answers to his queries. With regard to manuring, however, there can be no doubt that ground cannot be *too rich* for the vine. What kind of manure is best adapted to the vine, requires the test of experience. I experimented upon three vines, a short distance from each other in like situations, and upon same soil—a rich sandy loam. To one I applied *liberally*, unleached wood ashes, three or four times a season; to another, animal manure; and to the third vine, I applied liberally, long unfermented barn-yard manure.

The animal manure produced a luxuriant growth in the vine, and enlargement of the grapes, which exceeded any thing I ever witnessed in the Isabella vine, notwithstanding the severe drought this season. The vine "ashed," was also luxuriant, though not equal to the first vine, but more thrifty than the vine manured with barn-yard dung. I do not believe that ashes are congenial to the vine in *all* soils, but in a sandy soil it certainly is. Animal manure, however, will answer in any soil, and I believe for any crop. To other vines I caused soap suds, &c. to be applied, which I have found of great service.

Few cultivators consider, that the roots of the vine extend along the surface of the ground as far as the vine extends above the surface, and consequently the vine receives its nourishment from a considerable extent of ground. I was requested, a few days since, to examine a vine, which appeared sickly, and upon which the grapes were withering, although not half grown. I was told that the vine had been "well manured." On examining I found that within two or three feet of the vine the ground had been made rich, but beyond that distance, the top soil had been removed, in levelling the ground, and of course the steril subsoil alone left to nourish the vine. I need only add, that the owner understood the culture of flowers better than the vine.

My mite of information on this subject, is furnished with the hope that it may call forth the necessary information in relation to the culture of the vine.

BROOKLYN.

N. B. Since writing the above, I have examined the vine to which I applied animal manure, and find that it has several small bunches of grapes just formed, being a *second crop.* This, I presume, is owing to the extreme richness of the earth.

Culture of the Mulberry.

J. Buel—Sir—Considering your manifest anxiety for the progress and improvement of agriculture, and your known patriotism for American enterprise and independence, I am encouraged to venture a communication for your paper on the mulberry cultivation and the growing of silk, for the information and encouragement of those of your readers who have and are on the eve of commencing in the silk growing enterprise.

There is no necessity for saying, at this late hour, that the cultivation of the mulberry and the growing of silk, will soon become an important branch of useful industry, and a source of wealth to the United States, for it is already acknowledged by universal consent, that American climate and soil is as congenial to silk growing, and the sons of America as well calculated for agricultural and manufacturing operations, as any nation in the world.

You are no stranger to Yankee enterprise, and Connecticut perseverance, and you are therefore aware that they have done wonders in that state in silk growing operations for some years past, having realized a profit with no better food for the silk worm than the common white mulberry; but recently, however, the morus multicaulis was offered them, and they commenced testing its qualities and estimating its real worth, and their long experience in the use of the mulberry, had qualified them to decide correctly; and when they become thus satisfied with its superior quality and worth, and found, by experience, that the roots will endure our winters standing in the earth, and send forth an increased number of stalks every year they adopt its use, and push forward its cultivation with all their energy and skill, are now multiplying and vending it by thousands and tens of thousands, and, I am informed, many have commenced cutting down their white mulberry, and throwing them away, as no longer of use.

And, sir, I am prepared to say, without fear of contradiction, that the deliberate conclusion and doings of those so immediately and deeply interested, will speak volumes that nothing can prevent from being heard and felt in every part of this republic.

You are aware, I conclude sir, that a special committee of congress, in a late report, have informed us of more individuals and companies already engaged in this enterprise than is generally known, and in some states are companies extensively engaged in raising the mulberry, feeding the silk worm, and manufacturing silk goods of a superior quality, and with an encouraging prospect. And this same committee, in their report, speak decidedly in favor of this cultivation, and urge the propriety of increasing this business in every state, not only as a profit to those engaged in it, but as a source of wealth to the United States, which will add another link to the chain of our independence.

Very little is known in this region about the cultivation of the mulberry, or rearing the silk worm. Something has been attempted, a few years since, with the morus alba, (common mulberry,) but with little or no profit, the cultivators having no faith in the durability of the morus multicaulis, or Chinese mulberry.

There has been a prevailing opinion not only here but elsewhere, that the morus multicaulis is too tender a tree to endure our northern winters, yet there has been some honorable exceptions to the opinion; and as its history informs us it was introduced into the United States from two different places, we are therefore induced to believe that one kind is hardier than the other, from the fact that the kind we have, endured well the two last winters.

We commenced the cultivation of this mulberry in the spring of 1836, with 250 small trees, and 1,500 cuttings, all morus multicaulis. The first winter we left 20 trees standing in the open field, and unprotected from the weather, and cut down to the ground 34 trees, covered the stumps with a trifle of straw manure. They all lived and did well. Those we cut down to the ground sent out from their roots, the next spring, an increased number of shoots, some of which, in that season, growed about seven feet high, the fall after which was last fall, we cut all our trees down to the ground, and buried the tops in earth till spring, for cuttings and layers, in order to increase our trees more rapidly, and we have succeeded this season far beyond our expectations. Our trees will now number about 20,000, and an equal number of cuttings.

No tree or shrub that we have been acquainted with, is more tenacious of life or easier cultivated, or can be more rapidly multiplied than the morus multicaulis, and we consider the kind we have will endure our winters as well as our forest trees in general, under similar circumstances. It is to be desired that all our farmers commence the cultivation of the morus multicaulis, without loss of time, and we do think they would if they were more informed in reference to its worth, and ease with which it may be cultivated.

One of the letters accompanying the late report, say it is no more to cultivate an acre of land with the mulberry, than with corn. If each farmer would devote only one acre of land to the morus multicaulis, it would yield him from 100 lbs. to 300 lbs. raw silk a year, in proportion to the fidelity with which the cultivation and feeding is performed. But assuming the lesser quantity, (100 lbs. from an acre,) it would yield a greater profit than any other product from the soil.

If the farmer can be induced to believe that these estimates are correct, he would not fail to commence with the morus multicaulis, and we have estimations of this description so often repeated, and from sources that ought not to be doubted, we can hardly question but that the farmers will wish to embark in this enterprise, if they can know where the best kind of morus multicaulis can be found.—It is truly a scarce article, although many thousands have been imported, and hundreds of thousands grown in this country, yet the demand has not been supplied, and it is doubtful whether it will be for some years to come. The more that is known of its worth, the greater is the demand; although it multiplies rapidly it cannot keep pace with the call.

We can now spare a few thousand trees and cuttings, to those who first apply; and if any of your numerous subscribers wish a few hundred of each, the sooner they let us know it, the more sure they may be of accommodation. We have multiplied them so fast, that we will afford them considerable lower than we had to pay when we purchased in 1836.

A writer in the Farmer and Gardener, advises, as the result of experience, to purchase the mulberry in the fall of the year. He says, this mulberry is so tenacious of life, that if it is kept through the fall and winter buried in the ground to the depth of 9 or 12 inches below the surface, it will be just as fresh in the spring as when first taken up out of the ground; and then his trees or cuttings are on hand, and he can have the benefit of the entire season of growing, without that danger of delay others have suffered who put off their purchase until spring of the year; and the opportunity we have had has led us to the same conclusion.

We have fed a few silk worms every year since we commenced the cultivation of the mulberry.—We do not discover any necessity for the use of the hygrometer or thermometer. We find this worm to be an animal of life, and wants food for its support, and needs a rational proportion of attention, like other animals, and the better they are attended to the better will be the result.

Our second crop this year are now winding their cocoons in very good order. Yours, respectfully,

S. E. GIBBS & SON.

Troy, September 14, 1838.

Merchant Mills, Nelson Co. Va.
Sept. 10, 1838.

Sir—The drought in this region is distressing. Our clover fields would burn freely. Our corn crop will be considerably short of half an average crop. Our tobacco crop is nearly a failure; and added to all, on the morning of the 4th inst, we had a frost that killed vegetation entirely, in low frosty situations. "We are rather in a bad box here."

WM. MASSIE.

Turnip Culture.

Vergennes, Sept. 4, 1838.

Worthy Sir—I perceive much said in the Cultivator, on the subject of raising the English turnip. I here state my method, which for five years has not failed. About the 20th June I go into my sheep pasture, and plough a piece of sward land, run a fence round it, and yard my sheep, 250 in number, six or eight nights, from sundown until sunrise.—By the 4th of July I sow the seed, harrow it over, follow the harrow with a hoe, and turn all the green clods; then yard the sheep several nights, until the ground is trod hard; then sow with lime, plaster or ashes, or any or all of them mixed. When the plants come up, if the fly appears, dust it over with the above articles in the morning, when the dew is on them; continue until the rough leaf appears, when the work is done, except thinning the plants.

I prefer a light dry loam. Such land will produce three crops of corn, wheat, flax, or what you please, in succession, with plaster. I take up a piece, and stock down one each year; by this process you rarely discover a fly, and if the field is surrounded with grasshoppers, none will enter.

REUBEN WHEELER.

Ketch Mills, Sept. 10, 1838.

Dear Sir—I wish you to have the goodness to answer the following questions, relative to the mulberry:

1st. What is the present price of the Brussa mulberry, and in what proportion is the annual increase in good land?

Answer.—From 25 to 50 cents.

2d. How does its habits differ from the morus alba, and the multicaulis?

A. It is believed to be more hardy than either,—leaves intermediate size.

3d. Where can it be obtained?

A. At the Albany Nursery.

4th. Have you confidence in the prospect that the culture of silk will be a permanent business in this country?

A. Yes.

5th. What is the prospect for the price of the mulberry tree next season?

A. There will probably be very little variation in the price of the best varieties.

6th. What legislative enactments have been passed of late in Pennsylvania, for the encouragement of the culture of the mulberry?

A. A bounty has been offered on silk fabricated in the state.

Respectfully yours, &c.

HENRY ELLSWORTH.

To Jesse Buel, Albany, N. Y.

Crops.

Johnsonsburg, Sept. 14, 1838.

Dear Sir—Winter wheat came in first rate, although there was not as much sown as formerly, on account of the Hessian fly having destroyed much the year previous. There were no poor pieces, but a great many good. There is a worm, however, discovered to some considerable extent—as to country—not, however, having been very destructive this year. Winter rye-straw very fine—expectations before harvest, great—not realized however—much of the grain shrunken—not more, if half a crop. Oats light.—Spring wheat—some—very few pieces tolerable—the remainder *absolutely poor*—some say the fly injured it early, and the worm is found in much of it. The latest sown the best—the most of it much shrunk—rusted. Corn never looked finer or grew faster than it did here the forepart of the season, and the prospect was a super-abundant harvest. The drought, however, has hurt it some, but still our farmers say, there will be more corn in fifteen miles around, than there has been in any for five years past. Potatoes very poor—next to nothing. Buckwheat, on the low ground, cut by the frost, and seriously injured; on high ground, good—will be half crop, if not more. Pumpkins very few, and but few apples. Hay, reasonable quantity. The second crop of clover, for seed, very little—drought and grasshoppers ruined it.—There is a good deal of old corn in this county and Sussex—scarce any grain of any other kind, (old.) We shall be very far from starving.

We suppose the worm in the wheat is the grain worm, and many think it was brought here in the summer wheat. The most of the spring wheat was brought from near Utica, N. Y. last year—something like 250 bushels for seed—the most of it was sound, and the crops were good. A great deal more was sown this year, and the worm is in a great deal of it. Could the worm be brought in that way in the seed, or has it, in its peregrinations, reached us, and will it destroy all our wheat? I see nothing to save us yet, unless it be the quick lime, of which you appear to have some doubt. I fear that we shall be scourged heavily and severely, as this is a good wheat section. We wish all the information all the world can give us on this subject.

How long does this worm continue in any place? Is it a passing traveller, or does it delight to sojourn a long time in a place? It has just made its appearance here. Will it be likely to do much damage next year? Will you please to invite all the information that can possibly be obtained on this *all important* subject. Our farmers are preparing to sow largely this fall, as their wheat crops were so fine. I tremble for them. I fear the worm will be destructive.

There is a great deal of limestone in this section of country, and a great many low places, marshy, boggy, &c.; there are many large beds of carbonate of lime, said, by geologist Rogers, who surveyed our state a year or two since, to be a deposition from the water. It appears to be a bed of stiff morter. Much of it, Mr. R. says, contains 50 parts lime, 38 of carb. acid, the remainder sand, &c. Do you think this would require the action of heat to make it valuable as a stimulator. It has been used some, and always to a disadvantage, and I think always injudiciously, as too large quantities were applied in a place, so that vegetation was destroyed, by being thrown up to dry; and when dry it will become, by a little beating, very fine. There are millions of loads of it within ten miles of this place. But I must transgress no longer.

Yours, respectfully, R. BYINGTON.

P. S. Can Green's cutter be had in the city of New-York, or where? [Yes—at Thorburn's.]

[Mr. Byington's questions in regard to sheep, will be answered by letter.]

EXTRACTS.

Dry Rot.

THE PROPER SEASON FOR CUTTING TIMBER.

[*Abridged by the Baltimore American from Silliman's Journal.*]

"The marine establishment of our country has no more fatal enemy than what is termed the *dry rot* in timber, and we know of nothing which would be productive of greater practical benefit than the invention of a method by which it may be prevented. The writer of an article in Silliman's Journal, for April last, presents some valuable facts connected with the subject, the deductions to be drawn from which may be productive of highly beneficial results. After adverting to the superiority of the timber of ancient times over that of the present day in point of durability, as a matter ascertained, the writer proceeds to assign for it a reason which, he thinks, is to be found in the time of the year at which the wood is cut. An opinion has long prevailed that the winter is the proper season for cutting ship timber, but if the views of the correspondent of the Journal be correct, this long received notion is erroneous. To prove this, he adduces facts that have come under his own observation, which go to show that so far from its being proper to cut the wood intended for ship building, in the winter months, the more remote the time of cutting is from mid-winter or December, the better. He states, that in the year 1810 he had under his direction the preparation of the timber for a freighting ship, and that he caused it to be cut during the month of December of that year. At a subsequent period it was ascertained that additional pieces were required, some of those cut in the first instance not being fit for the purpose. At the time when the last cutting took place the leaves were full grown and the bark would peel. In July, 1811, the vessel was launched, and in the following autumn was sent to sea, and after the declaration of war was despatched to Middletown, Connecticut, where she remained until the peace in 1815. In the spring of the latter year, when she was to be fitted out for service, on examination it was found that the timbers which had been cut in December were so much affected by dry rot, as to render rebuilding to a great extent indispensable, whilst the pieces prepared when the trees were in foliage were perfectly sound. Such was the perfect condition of the timbers prepared in the summer, that the spikes which had been inserted appeared, on being drawn out, perfectly bright—those which had been driven into the winter cut portions being oxydized to a great extent. The ship sunk some years afterwards at sea, a miserable hulk, in consequence, as the writer thinks, of the rottenness of the portion of her bottom which had remained untouched at the time she was repaired.

"A case so striking induced our author to believe that the common opinions about winter cutting were erroneous, and caused him to make some experiments in order to test the cause of the dry rot, and being doubtful of the correctness of the botanical theory, according to which it is supposed that the sap recedes to the roots during winter, he took, in June, 1815, some pieces of oak cut in June, which he placed over a fire. He found as the heat increased, that on the ends of the sticks there appeared a wet circle describing the exact thickness of the *alburnum*, or portion of wood outside of the heart, and that steam rushed violently from the tubes of that part, whilst there was but a slight appearance of vapor over the heart wood. In December of the year he tried a similar experiment, and found the steam to issue from the heart wood, whilst the alburnum remained perfectly dry. From these experiments it appeared evident that in summer the sap is in the alburnum, and in the winter in the heart wood, whither it had been conveyed by some process of nature not understood, and not in the roots as had been supposed. Subsequent observations have proved to the writer, that when growing trees are trimmed in summer, the rot which ensues begins in the alburnum, whilst in those trimmed in winter, the decay takes place first in the heart wood. In further support of the new theory, reference is made to the fact, that chesnut rails, which are usually made in summer, last a great number of years, whilst posts made of the same material, which are generally prepared in winter, rot in seven or eight years. As a mode of ascertaining the season at which the ancients cut their trees, it is suggested, that on examination of ancient timber it will appear, that the powder post, as it is called, and the dry rot, will be found in the alburnum, and that the interior of the heart wood will be found perfectly unaffected. The following experiment is mentioned as illustrative of the effect produced on the outer or inner portion of the wood, according to the season of cutting. Take two saplings, one of which has been cut in June and one in December. By placing a piece of each in the garret, and a piece of each in the cellar, it will be found in about three years, that in the garret the powder post will have appeared in the alburnum of the one cut in June, and in the heart wood of that cut in December, whilst, in the cellar, the dry rot will exist in accordance with the same rule. The conclusion to which the writer comes is, that June is the best time for cutting ship timber, and that in proportion as we recede from that month will be its liability to decay. The subject is one of vast practical importance, and there is reason to believe that the perishable character of the wood of our country used for ships, is to be attributed, in a very great degree, to the fact of its being cut in winter."

On an Economical mode of Furrow-Draining.

[*From the Edinburgh Quarterly Journal of Agriculture.*]

Every attempt at the introduction of economy in farming operations, if founded on practice, deserves commendation. On this ground, the following economical mode of making furrow-drains claims especial attention from those whose locality affords flat stones.

Suppose a piece of land containing two ridges, of 15 feet each, one whole ridge and two half ridges, divided by two furrows. The drain is made in this manner:—Gather up the ridges with a four-horse plough, to make these furrows wide and deep. If gathered from lea, a crop may be taken the year previous to the commencement of the drainage. This ploughing leaves the furrows 16 inches wide at the bottom, and if the furrow-slice *a a*, fig. 52, on each side, has been ploughed one foot deep, and laid over at an angle of 45 degrees, their tops will be 32 inches apart. A line stretched from the crown of one ridge to that of another, will give the depth of the ploughed furrows 22 inches below the crowns of the ridges. This ploughing is only a preparation for the ultimate making of the drain. The drain is then made in this manner, on strong clay soils, which alone can resist the abrading effects of running water. Leave a scarcement of one inch on each side of the bottom of the furrow left by the plough. Cut out the earth 14 inches wide, perpendicularly, with the common spade, 10 inches in depth, *b b*. Then throw out the bottom of the drain with a narrow-pointed spade, 5 inches more in depth, *e*, and 4 inches in width, leaving a scarcement of 5 inches on each side of the spade; and the cutting of the drain, whose bottom is now 37 inches below the crowns of the ridges, is then completed. The drain thus made is filled in this way:—Take thin stones, such as strong grey slates, or thin flags, and place them upon the 5-inch scarcements left by the narrow spade, as *d*; they need not be dressed at the joints, for one stone can be made to overlap the ends of two others. They form the top of the conduit through which the water in the drain flows under them. The drain then may be filled up in the usual manner, with the plough and spade. The expense of making this kind of drain is, for spade-work, 6*d*. per rood of 36 yards in length. A Scotch acre contains 32 roods of furrow, at 15 feet apart, which gives 16*s*. for spade-work; 12 tons of flags, of an inch thick, will cover the 32 roods, which, at 4*d*. per ton, is 4*s*. more,—in all 20*s*. per Scotch acre, including the laying of the flags, which is estimated in valuing the spade-work. Fig. 52, will give an idea of this drain, after the above description.

Fig. 52.

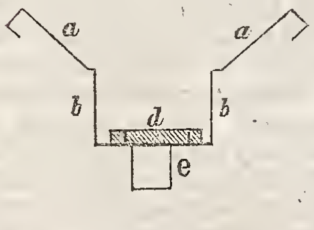


Fig. 53.

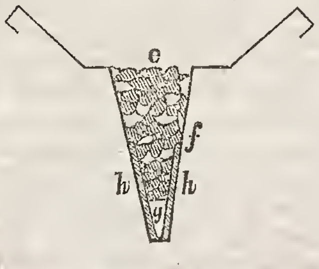


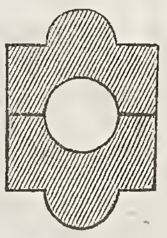
The drain represented in fig. 53, is thus made, and it is applicable to every species of soil. After ploughing the furrow, as already described, the spade takes out a trench from the bottom of the ploughed furrow, 8 inches wide at *c*, 16 inches deep *f*, and 3 inches wide at the bottom *g*. The depth will thus be 38 inches below the crowns of the ridges. This drain is filled with flags *h h*, set on edge, meeting at the bottom of the drain, reclining against the sides, and kept asunder by a stone of any shape, acting like a wedge between the flags, as represented in the figure. The remainder of the drain is filled with riddled stones, the riddlings being kept on the top, and covered with any matter, and then earthed over with plough and spade, like any other drain. The expense of the spade-work is about the same as of fig. 52; the stone-work will of course be more, but how much more has not been so accurately ascertained as to be confidently given to the public. Even at £2 per Scotch acre, this would be a substantial and cheap method of furrow-draining. T. S.

On Making Draining Tiles of Peat.

[*From the Edinburgh Quarterly Journal of Agriculture.*]

An ingenious spade has lately been invented by Mr. Hugh Caldarwood, Blackbyres, Kenwick, Ayrshire, for cutting draining tiles of peat. The instrument is worked very easily, and forms the tile with one cut of the spade; the tiles being cut *one out of the other* expeditiously, and without waste of material. Their shape is something like clay tiles, but more massy. They are dried in the sun during summer, lying flat on the ground, and may be stacked like peats, ready for use when required. When properly dried and hardened, wetness will not soften or decompose them. Peats are frequently found in mosses which have been buried long ago by accident, still hard and fresh; and those that have been used for draining upwards of thirty years ago, have been taken out of the drains unimpaired and solid. It has even been asserted, that a well dried peat has been boiled for six months in a boiler at Catrine Cotton-works, which was taken out after that period solid and uninjured. There is no doubt, however, of the capability of dried peat to resist moisture. The large stacks of peat formed for the use of families in Ireland, where coal is unusual or scarce, are never thatched. The invention of this spade tends to render the draining of moorish lands more practicable than hitherto, as with it a farmer may cast two or three thousand tiles a day, within a very short distance of the ground he intends to drain, at one-fourth or one-fifth less expense than he could furnish himself with the same number of clay tiles; the frequent want of clay in such districts rendering the manufacture of clay tiles at hand impossible; and the cartage of them from the kiln to a great distance to the land is at all times an expensive operation. When laid in the trench, the peat tiles are placed with their grooved faces opposite each other, one of them serving as a sole, as in the figure. We understand that a considerable number of Calderwood's spades have been working this season in Ayrshire; and if experience prove their utility, they will no doubt get into general use in peaty districts. Specimens of the tiles and spade have been lodged in the museum of those enterprising friends of agriculture, Messrs. Drummond, Stirling, and we believe they may also be seen in the hands of Messrs. Samson and Company, seedsmen, Kilmarnock.

Fig. 54.



The article which follows goes to prove three facts, of primary importance to the farmer, which we have strenuously endeavored to inculcate, viz:

First, That the resources for manure, on almost every farm, are sufficiently abundant, when properly husbanded and applied, to keep up, or improve, its fertility;

Secondly, That blending unfermented dung with earth, or the soil, accelerates its decomposition; while,

Thirdly. A vast amount of fertilizing matter is saved by such admixture being made, *before fermentation has taken place*—the earth "absorbing and retaining that excess of putrescent fluids and effluvia which is otherwise lost by filtration and evaporation; that is, by soaking away and drying up."

[*From the Farmer's Cabinet.*]

Manure.

WHAT IS THE GREATEST QUANTITY OF MANURE TO BE OBTAINED FROM GIVEN MEANS?

Mr. Editor—There are in agriculture, as perhaps in every science, some leading propositions, calculated in a particular manner to arrest attention by their prominent importance. Such I hold that of a "Subscriber" in your May number—"*What will an acre of land produce?*" and also the question which heads this article.

Were it possible at once to afford a complete and palpable solution to these two propositions, what mind can calculate the vast increase of treasures that would instantly become accessible to humanity? As, then, we cannot inquire too strictly, or know too much regarding them, I propose, after recapitulating a few of the principal statements of a "Subscriber," concerning the latter question, to furnish my own experiments upon the former.

He informs us that a single acre of his land, *with abundant manuring and superior cultivation*, was made to produce the sum of $348.40 per annum, for five successive years, besides the vegetables used in a small family. He further states, in substance, as his present conviction, that the quantity of soil cultivated has nothing to do with the secret of gathering money out of it; that "this altogether depends on a judicious selection of soil, *on the facility of obtaining manure*, and on the proper application of it as food for plants," &c.;—that he found, by actual experiment, made upon a large scale, "that
the profit of capital laid out in land produced an inter
of only *five* per cent per annum, the capital laid out
manure upon the same land produced *twenty* per cen

Now, my own experience, as I shall presently sho
abundantly comfirms the probable accuracy of all the
statements. Let us distinctly understand, then, that
is not the great quantity of land, but *the abundance*
manure upon a little, that is alone required to give weal
and independence; that the man who owns five or s
acres, may (according to the above data,) with the a
of manure and good management, draw from $1,800
$2,000 from them each year, while he of a hundr
acres may scarcely obtain half of it upon the comm
plan.

But where is the requisite manure to be obtained th
shall so suddenly and surely enrich the farmer? In r
ply to this, I will simply give my own experience, a
by it endeavor to convince the reflecting farmer wh
amount can, and in fact *has* been made from means i
comparably more limited than is generally imagined po
sible.

Previous to 1829, I had followed in Philadelphia a s
dentary occupation, which, by excessive application
it, had so enfeebled my constitution, that I was oblig
to seek in the country for that measure of health whi
I might no longer hope for in the city. So I bough
with my scanty savings, a small place of ten and a ha
acres, and moved upon it the same fall of 1829.

Not being acquainted with farming, I hired a man
plough two and a half acres, and sow it in rye. Th
cost of seed and labor, in putting in, gathering an
thrashing the said crop, was $8.56. The crop yield
five and a half bushels of very poor black rye, fit on
for hay feed—say at forty cents per bushel, (as goo
rye was then selling at fifty and fifty-six cents p
bushel,) was worth $2.20, and the nett loss sustaine
upon farming the ground was $6.36. The season wa
moderately good for grain, and the two and a half acr
rather a favorable specimen of the rest of my land
I planted a potato patch the following spring, (1830,)
about the fourth of an acre, which I manured in th
hills with one load of marl only, and the crop yield
but three and a half bushels!

Being a total stranger to the nature and character o
soils, but having previously, from some cause, ente
tained the notion that land in general produced abo
twenty-five bushels of wheat, or forty bushels of cor
or four or five loads of hay to the acre, the conviction
had now received of the absolute worthlessness of m
land fell upon me like the shock of a thunder-clap. Di
couraged by the greatness of my disappointment, bu
not quite confounded, I determined that manure, in f
ture, should be every thing to me, and stand in th
stead of both land and crop. Being greatly improved i
health, by the change of situation and exercise, I plie
my avocation with increased diligence for the maint
nance of my family, and made it the amusement of m
leisure hours and leisure moments to collect from ever
corner, and pannel of fence, every thing that I imagine
could furnish a vegetable nutriment, and placed it i
the cow yard, so combined with the litter as to absor
and retain every thing of the putrescent character tha
might be deposited there. By such means I have gon
on, every year increasing the quantity of my manure, t
an extent that I believe astonished most of my neig
bors. The following is a sketch of the means I posses
ed, and the methods I took to obtain manure for the pr
sent year.

I commenced last summer by collecting into the oute
part of my hog pen every thing of the weed kind I coul
find about the place, till I had a layer about twelv
inches deep, which I covered with a layer of earth abou
five inches thick, continuing the process till the pen wa
filled to about two and a half feet deep. In the fall I
littered my loose corncobs and the principal part of th
buckwheat straw into the pen, interspersed with layer
of earth in the same manner. The two stalls of my sta
bles I served also the same, taking care to save therei
all the chaff and refuse straw after thrashing. In thes
stalls I poured weekly, through the fall and winter, (fo
I had no cattle in them except in bad storms,) the soap
suds and such putrescent fluids that might be obtained
keeping the corners and outsides, and under the man
gers carefully saturated.

As soon as my corn was gathered in the fall, I cut th
stubs close to the ground, and wheeled them immedi
ately, *while yet heavy*, into the barn-yard, where I pack
ed them in every part of it, and also under the shed, be
ing an area of ground about forty feet by twenty, and i
a few days covered them also with a layer of earth
from a fence-row, close by, to the depth of about eigh
or ten inches. Upon this earth I foddered my thre
cattle during the winter, occasionally depositing mor
earth upon the litter as it collected there.

Your readers will readily judge, that the object of a
this preparation was not so much for the sake of savin
the materials collected there as to obtain a menstruum
or rather *sponge*, if I may so call it, calculated to absor
and retain all the urine deposited in the yard during th
winter. The compost masses, however, or layers, thu
collected together, are not to be considered as manur
prepared for the soil, but only as *materials* that requir
to be thoroughly *mixed*, in order to reduce them to
state fitted for a rapid and complete incorporation wit
the soil. Accordingly, with this view, I commenced lat
in April the operation of turning it, which, from its hav
ing become closely packed to the depth of twenty inches
with the stalks at the bottom, could only be done wit
the aid of a grubbing hoe, turning it in strips about a
foot wide, reaching across the yard, and throwing th

sened manure back a sufficient space to allow a hch between, wide enough to work in. After remov- the whole cover from the stalks, along a strip, as ore mentioned, they were easily grubbed up, by first ting them through all along the solid edge of the strip h the hoe, it being made pretty sharp for the pur- e. In addition to this pile of yard manure, I have emptied the contents of my hog pen and stables, nding the pile several feet, and lying upon the und, when first loosened, more than two and a half deep. Of this manure I have used sixteen loads spring, for truck and garden, and, judging from the of the pile yet remaining, there cannot be less than y loads, which, being turned once more, I intend to for wheat next fall.

n this manner, from only three head of cattle, and the ening of four hogs, I have made from seventy to ty-two horse loads of manure, the highly fertilizing perties of which are abundantly attested by my own ner experience. I will not say that it is stronger than best barn-yard manure, but from its closer affinity he nature of the soil, and greater facility for being idly combined and incorporated, without loss by eva- ation, I have no doubt it will be frequently found, n trial, more effective and more durable.

the process of turning manure, thus prepared, I it of the highest importance to mix well the earthy vegetable parts together. Few persons are per- s aware how rapidly the earth facilitates vegetable omposition, and to what a surprising degree *it ab- s the excess of fertilizing effluvia,* which must other- be evaporated during the process of decomposi- . This circumstance, I believe, taken in connexion the careful economising of all animal excretions, stitutes chiefly the great secret (I might, perhaps, *alleged* necromancy,) that has added already so h verdure to my previously exhausted soil, and been rofitable to me, and so surprising to my neighbors. o farmer can imagine, that has not tried the experi- t, what a prodigious quantity of rich, vegetable, and ous earth may be collected from corners and by- es which lie out of the way of cultivation, and ch, from their retired position, have perhaps, never uch as attracted his notice. All such refuse trash, fibrous earths and weeds, by being conveyed to his -yard, at intervals, during the fall and winter, and ciously combined with its contents, will be converted a rich, fertilizing, and durable manure, merely by rbing and retaining *that excess of putrescent fluids effluvia* which is otherwise lost by filtration and oration; that is, by soaking away and drying up.

W. H.

ittstown, Salem Co. N. J. May 20th, 1838.

---

the Means of Increasing the Fertility of Land.

he productiveness of any soil, we think, depends en- y on its natural or artificial capability of retaining transmitting its moisture, the vehicle at least by h nourishment is conveyed to plants. This pro- ive power may therefore not only be continued in reatest vigor, but greatly increased by proper ma- ement. When we by any means give to the soil a anently increased vegetative power, we also in- se the yearly produce which it yields.

ome soils produce large crops often repeated without ure, five crops of corn and a fallow are the condi- s entered in some leases in the neighborhood of Wis- in Lincolnshire, while other land will produce ing without great expense of culture and manure, will an excess of manure make such land perma- ly productive; but if we change its constituent parts e addition of those earthy materials of which it is ient, so as to bring it nearer to the nature of those which we know to be fertile, then we shall perma- ly increase its productive powers.

ater being the vehicle by which nourishment is con- d to plants, the soil, whose constituent parts is best ted for retaining a sufficient supply and transmit- a proper portion in very dry weather to the plants ing in it without holding it in injurious quantities e time of very wet weather, it is possessed of the iple of vegetation and will be found to be of the productive nature. Such a soil will give not only ess to support the plants, but will facilitate the th of their roots in search of moisture and nourish- to the greatest depth.

ere is not an individual who cultivates a garden who exercises his judgment in its culture, but knows he addition of clay gives cohesion to sandy or gra- soils, and that sand and gravel when mixed with a y soil diminishes its tenacious property; and that changes thus effected permanently increase the uctive powers of both.

our endeavor to improve barren soils, we should ine them in connexion with fertile soils in their borhood, on the same geological formation, and ifference of their constituent parts may lead us to eans of their improvement. If the cause of steri- e owing to some defects in their composition, these ts should be supplied. An excess of silicious sand proved by the application of clay, peat earth, or eous matter, cold well rotten manure, and rolling mpling with sheep or other stock, to consolidate xture.

en clay is in excess, it is remedied by the appli- of sand, chalk marl, or burned clay, light un- nted manures, and perfect pulverization, to make il friable. An excess of vegetable matter as in soils, in a dormant state, is corrected by burning, e applications of clay, sand, calcareous matter, gravel, rubble, or anything heavy, to give firmness to the soil. Lime not only destroys the injurious effects produced by sulphate of iron, which abounds in some soils, particularly in those of a peaty and silicious gravelly nature, but is said to convert the sulphate of iron into a manure. None of these applications, however, will have the desired effect, unless there be first a perfect subsoil drainage of all superfluous moisture conjoined with a perfect tillage. To alter the nature and properties of the constituents of any soils may be more expensive than to manure it; but the effect of the former will be lasting, while that of the latter is transitory; the one permanently improves the nature and quality of the soil, the other only imparts a temporary excitement to force a crop for a year or two.

The materials necessary for the permanent improvement of the soil are seldom far off, and the expense, though in some instances considerable, is soon repaid by the permanency of its increased fertility; the manure applied afterwards has a much greater effect, the expense of cultivation is greatly diminished, and the capital laid out is soon restored by its yearly increased produce. By these alterations we store the earth with hidden and inexhaustible treasures, which, invisible to the eye, put forth their strength and give us the evidence of their presence by the effects produced on vegetation.

In the process of vegetation, nature supplies soil, water, light and heat; but the matter composing the soil may not be in such a state as to receive, and transmit these in such quantities as will produce a healthy vegetation.

Man may regulate the supply by the cultivation, and by altering the texture of the soil.

When the materials of which the soil is composed are in proper proportion, the soil is most productive; when any one of the ingredients is in too great a proportion, the soil is unproductive.

Pure clay, silex, or lime, we have before stated, are barren, if they are found alone; but if they are mixed together, having a due portion of water, the influence of the sun, and a proper admission of air, (which are the prime movers in vegetable life,) a fermentation amongst the materials is created; and if vegetable and animal manure in a state of decomposition be combined with these, the soil which was sterile when separate will become productive when combined, and this mixture of materials and mechanical alteration will change the texture, and improve the quality of the soil.

Neither the clay, the silex, nor the lime are decomposed by this process, but the soil composed of these materials in proper proportions has the power of combining with, and decomposing the vegetable and animal matter, the water, and air which it contains, and produce results which afford the necessary food for the growth of plants.

When the particles of earth which compose the soil are separate from each other, or well pulverized, it holds the greatest quantity of free or available moisture, and readily transmits it to the plants which are growing in it; but when the particles of the earth are closely packed together, like new made bricks, it neither can receive moisture, nor will it give out that which it already possesses.

Good soils are naturally possessed of certain powers, with which, by the aid of husbandry, we can produce certain effects; on poor sterile soils, these powers may be conferred by artificially altering their texture.

When the fluid in the soil is so connected with the fluid in the plant, and gives out to it a constant and healthy supply, then we say the soil is in good condition.

Manure applied to the soil increases its vegetative powers, but the way in which it acts is not well understood. The process of the small rootlets are so very minute, that no crude substance can pass through them; it can therefore, only be taken up by them in the form of water or gas, and be absorbed by the leaves.

Well rotten manure gives an unctuous or cohesive property; but when in a loose or strawy state, it gives a porousness or looseness to the soil.

All mineral manures, as lime, chalk, marl, sand, gravel, ditch mould, road scrapings, and earthy matter, act on the soil merely as an alterative, by changing the constituents of the soil and improving its texture, and by giving it an increasing power of imbibing and decomposing water, air, and organic matter.

The most abundant ingredients in soil are sand and clay, and as a mixture of the one with the other tends to improve both, nature has so ordered it, that these are generally found in great abundance near to each other.

In the plastic clay formation, extensive tracks of sandy soil are found lying upon the brick clay; the soil of which is greatly improved by lifting up the clay, and spreading it over the sand at the rate 100 cubic yards to the acre.

There is also a considerable extent of this formation covered with flinty gravel, mixed with clay and sand, with a thin covering of black mould or peat earth for its surface, which produces heath and furze.

This lies near the clay, and the whole of this may be greatly improved by trenching, or otherwise mixing the sand and gravel with the clay below. The most of this is near the chalk, and would be greatly improved by an admixture of 80 or 100 cubic yards of it per acre. Chalk or lime destroys the pernicious effects of the sulphate of iron in the gravelly soil, and makes the soil which was worthless, so productive as to pay the whole of the expense in a year or two.

Soil that is chiefly composed of finely divided or impalpable matter, is greatly improved by the application of small stones, gravel, or coarse sand; as this prevents the soil from collapsing or consolidating during continual rain.

All alteratives should be put on the land in small quantities at a time, or if in large quantities it should be when the land in fallow; and these should be well mixed by repeated ploughings, or by Finlayson's harrow, which is an excellent implement for loosening and breaking the the fallow slice. The best way of putting on small quantities of materials for altering the texture of the soil is to make a mixture of them with the manure you intend to apply to the field; and these ought to be well mixed by laying them loose together, turning them several times, and fermenting them in the mass. When this is properly done, it should be carted and spread on the soil when in fallow, and be ploughed in and well mixed, so as to be completely incorporated with the soil.—*Morton on Soils.*

Construction of Ice Houses.

[*From the Farmers' Cabinet.*]

The July number of the Farmers' Cabinet, contains a request for some one to furnish an essay on Ice Houses; as I have some experience on that subject, 1 freely communicate my knowledge for the benefit of the public.

I have erected several houses, principally for the purpose of supplying the citizens of Wilmington with ice, and find the larger the house the better it will keep; and that those constructed under ground are much preferable to those built in the open air; and further, that a wet, humid atmosphere, is more destructive to ice than hot weather. In making an ice house, you first dig a cellar in the side of a hill the dimensions that you wish to make your house; the only rule to observe in this operation is, to make the cellar so that it will not hold water. If the situation is sandy, or if you come to a vein of sand about the time you arrive at a proper depth, no further care will be necessary; but if you find a stiff clay or earth of any kind impervious to water, you must make an outlet or abandon the place. This outlet may be constructed in several ways; if on the side of a hill, dig a drain and make it air tight by an inverted syphon; or the water may be drained into a well and pumped out, or you may sink a small shaft in the bottom of the house until you come to sand, and fill it up with stone. When the cellar is finished the walls may be made of stone, brick, or wood, to suit the convenience of the builder, always leaving a space of 8 or 10 inches between the sides of the building and the earth, to fill in with tan, charcoal, straw, cornstalks, or any other non-conductor you can get, but tan is by far the best article yet known.

Where expense is no object, the cellar may be made round, and the sides of brick, raised a few feet above the ground, and covered with zinc, sheet iron or tin, and some fancy ornament for the top.

A house 9 feet square in the clear, and 9 feet deep will hold 27 cart-loads, which will be sufficient for a large family. It may be erected in a few days by a handy laboring man, with the materials that can be found upon almost every farm. Dig a cellar, say 10 feet square, and 10 feet deep, then cut small timber from the woods the proper length, and build them up in the cellar after the plan of an American wooden house, keeping the space between the logs and the earth well filled with straw; raise the building two or three feet above the surrounding ground, so that the water will not get into the house, thatch the roof, and leave the gable ends open, for ice houses are often made too close at top, cover plentifully with straw, and you will have an abundance of ice through the season.

If the bottom of your ice house is clay or hard earth of any kind, it will be better to put in a few loads of coarse sand previous to filling the house. There is some difference of opinion among people acquainted with keeping ice, in regard to the construction of the upper part of the building, whether there should be a tight floor over the ice or not. My opinion is in favor of covering the ice well with straw and leaving the house ventilated at the gable ends, at least so open that the gas escaping from the ice will have an opportunity of passing away. SUBSCRIBER.

Theory.

[*From the Farmers' Cabinet*]

No man, however much he may repudiate theory, engages in any work without first having the theory of it established in his mind. Theory precedes practice as thought precedes action. One farmer spreads his manure a long time before he ploughs it in; another ploughs it under as it is spread, and another uses it as a top-dressing, while some are particular as to the time of the moon, when dung is put on the soil. Each has his theory and acts agreeably to it, and his success is not dependent on his having *no theory* at all, but on his theory being in accordance with sound reason; for there is always a reason why one way of doing a thing is better than another. Some allege that every thing that is printed about agriculture is mere theory, and therefore to be disregarded; those who entertain this opinion, certainly maintain a very unsound *theory*, and the sooner they sift all the knowledge they possess and have gained by their own individual and unaided exertions, from what they have obtained by reading and conversation with others, the sooner they will ascertain the sum total of their *ignorance*, which it is expected will so alarm them that they will see the necessity of rubbing some of the roughest of it off. O.

Practice vs. Theory, or the Hands vs. the Head.

[*From the Farmers' Cabinet.*]

"No divorce, I beseech you, my friends."

Having recently been present during a very interesting and amusing conversation between two farmers, about your "Farmers' Cabinet," I will undertake to give you some account of it, or at least a short abstract of the subject matter of it. They were both good, and pretty intelligent farmers, but their views of some things, and particularly of matters written or printed in regard to agriculture, were as different as the two sides of a bake-iron. The one was descanting on the benefits and advantages of the Farmers' Cabinet to farmers generally, and now and then he read a racy article from it to prove his position; the other contended that any thing printed on the subject of farming was mere *theory*, and of no use, but rather calculated to lead people of little experience astray from the good old way of doing things that had been practised from the earliest times. He said that these printed things only dissipated people's ideas and withdrew their attention from work, and he thought were ruining our young people by keeping them thinking all the time instead of working. On the other side it was contended, that teaching people to think enabled them to work to much greater advantage, and that all the improvements which had been made in the world, were the result of thinking, and that thinking was not at all incompatible with action, but on the contrary, was the very base and foundation of it, and that a discovery or improvement being made, the promulgation of it in print was doing the greatest good to mankind, as it tended to keep up the equilibrium of knowledge, and enabled one man to work with the tools of another without cost. At last the contest assumed the form of a regular combat between the Head and Hands; a little on the plan of that detailed by Esop, of the quarrel that took place between the Belly and the Limbs, when the latter fairly rebelled, and refused any longer to work for a fat and indolent Paunch, which they considered as entirely useless, and unable to provide for itself.—However, after a short trial, at keeping up separate establishments, finding it not to answer expectation, a truce ensued, and they agreed to go on amicably together, and found a mutual advantage in it. Now I suspect this contest between the Head and the Hands will terminate in the same way, by each returning quietly to the performance of its appropriate duty again, as members of the same indissoluble firm of "Head and Hands," each attending to its own department, while they are both working for the common good; for I should like to know what sort of a farmer a man would make either without a head or without hands. I was thoroughly convinced by the arguments of the parties, that every man in this free country has an undoubted right both to think and work, either jointly or separately, as much as he pleases, and that there is not much danger of our carrying either to excess; but above all I was confirmed in the conviction, that every intelligent farmer should write down the results of his experiments, and the cogitations of his mind, on agricultural and rural affairs, and forward them for insertion in the Farmers' Cabinet. X.

Science of Gardening.—*Continued.*

[*From the Alphabet of Gardening.*]

LIGHT.

It is common with gardeners to expose their tender frame plants gradually to the open air, by taking off the lights from day to day, for the purpose, it is said, of rendering them more hardy. Few of those, it is probable, who do so, are aware of the principal agent which renders the plant more hardy, and which, if I mistake not, is generally supposed to be cold or fresh air. This, there can be no doubt, assists in the process, and is indispensable to its perfection; but there can be as little doubt, that light is the main agent, as a few facts and a little reflection will prove.

The process of blanching salads depends chiefly on depriving the plant of light, by earthing up a portion of the stem, as practised with celery; by tying up the tops of the leaves, as is done with lettuce; or by covering them with inverted pots, as is done with sea kale. In all these cases, the plants are crisp, watery and tender, compared with others not thus treated but similar in all other circumstances, which are stringy and tough in their fibres, less juicy, and therefore hardy. No exposure to cold or fresh air would produce this toughness and hardiness, if the plants were kept in the dark; and no absence of cold and fresh air would produce blanching, if a strong light were admitted.

Complete blanching is only produced by complete exclusion of the light; but its partial exclusion causes plants to be pale and sickly, as in the shade of thick woods, or plants in a stove or green house accidentally placed so as to be shaded by others. In all such cases, plants are popularly said to be *drawn*, that is, they endeavor to push their branches as much as possible into the light, and being from deficiency thereof proportionably feeble, they increase in length without at the same time acquiring strength. A potato in a dark cellar will in this way send out shoots of some yards in length, but not much thicker than a writing quill. It is on this account, that the glass frames in hot-houses ought to be as thin as possible, and therefore iron is preferable to wood. More light also will pass through a sloping or level frame than through an upright one, and through a domed or curved roof than one that is plane; because the rays of light always go in straight lines from the sun.

This singular propensity of plants to turn to the light has been supposed to indicate something akin to animal instinct; but when the cause is closely examined, this will not appear to be better founded than that of a piece of writing paper bending into a semicircle when held to the fire; for both the motion of the plant and of the paper depend on the same cause—namely, the hardening and stiffening of one side, while the other remains soft and flexible. In the case of the paper, the side next the fire has its moisture carried off by evaporation more rapidly than the other side; and in the case of the plant, the side most exposed to the light is in the same way rendered more firm, contracted, and shorter than the one less exposed. The very long shoots of the potato in the dark cellar seem to be caused by the softness of the blanched substance offering no resistance by contraction to the lengthening out of the parts.

It will follow that all colour, flavor, smell, and nutritive qualities, depend for their production chiefly on the action of light. The red colour of forced rhubarb, which seems to be an exception, arises from the red matter previously produced by the agency of light being carried up from the root.

It hence appears, that the study of the laws and action of light is of the first importance to a correct knowledge of scientific gardening, as will further appear when we come to consider the use of leaves.

HEAT.

As it has been shown that the food of plants, in order to be available, must be fluid; and as heat is the cause of fluidity, its primary importance to vegetation must be obvious, for no plant could take up frozen liquids. The processes, moreover, of fermentation and putrefaction, by which are produced the supply of carbonic acid gas, humic acid, and nitrogen, indispensable to vegetation, cannot go on without warmth. It is well known, for instance, that beer cannot be brewed in frosty weather, because a due degree of fermentation cannot be effected on account of the cold.

The effect of heat on plants is very beautifully proved by the experiment of Du Hamel, on the rising of the sap in vines in spring. On a frosty day, when the sun shone on a cut vine, the sap flowed on the south side exposed to the sun, but not on the north side where it was in the shade. In Canada, also, where the frost recur, though on the south side the bleeding goes on, at least during sunshine. It is on this account in some northern climates, where the long sunny days succeed the thawing of the snows, as in Norway and Russia, that the gardeners are said to shade their wall trees from the midday sun in the spring, to prevent the sap being prematurely raised and again checked by the certain cold of the succeeding night, a contrivance which also retards the flowering till there is less danger from spring frosts. Such shelter will also be beneficial in protecting from the dry winds of spring.

Did these effects of heat, which must also in part be atributed to light, require any proof, it may be shown by two wine-glasses, the one filled with hot and another with cold water, in each of which is placed a similar hollow straw so as to discharge the water, when it will be seen that the hot water flows more rapidly than the cold.

The soil in this country, below where the frost usually penetrates, averages a temperature of 48°, or 15° above freezing, which is the reason why springs do not freeze, and not any quality in the spring water, which will freeze readily enough when taken from the well.

It is of the utmost importance to be acquainted with what is termed the *radiation*, that is, the spreading of heat, which arises from heat passing from a hot body to a colder one near it, as uniformly as water runs down a slope. This spreading of heat takes place between the surface of the ground and the air; and when the air is cold, though the soil be warm, it soon loses its heat, and dew or hoar frost is formed on the grass by the moisture diffused in the air, though previously invisible, becoming condensed or frozen. But when the sky is covered by clouds, this spreading and loss of heat is in a great measure prevented, and hence there is no dew or hoar frost formed on a calm cloudy night, as was first remarked by Aristotle.

It is on this principle, that garden plants are protected by matting, which stops the heat of the soil from spreading about and being lost in the air. Dr. Wells proved this principle by stretching a very thin cambric handkerchief two feet square, six inches above a grass plot; and he found on one night that it was five degrees warmer under the handkerchief than the rest of the grass plot; and on another night there were eight degrees of difference. Hence, great thickness does not seem to be so important in such cases, as the interposition of any screen whatever between the soil and the sky, provided always that the screen does not touch the soil or the plants to be protected. In this case it might carry off heat by conduction.

It is on the same principle that snow affords a protection from the severity of frost, the plants under snow having been found by Dr. Darwin to indicate forty degrees, that is eight degrees above freezing; hence some Alpine and Siberian plants, such as auriculas, do not bear exposure to frosts when unprotected by snow, so well as those which are natives of a warmer clime, and require artificial shelter.

It may be remarked, that hoar frost is never seen on a sloping hedge bank, on the side of an earthed-up row of celery, nor close to a garden wall, unless when the surface is already frozen, and that such places are always the first to thaw, beginning with the summit of a slope, evidently because the slope is unfavorable to the spreading of heat, while the garden wall stops it, in the same way as Dr. Wells's handkerchief did. Hence broad coping stones on walls are excellent for protecting wall trees.

Another reason for a slope or a hill being warme than a valley, is that cold air being heavier than warm air, the coldest air, always rolls down to the lowes situation; but if there be a brisk running stream in a valley it will prevent, in some measure, the stagnatio of cold air; injurious, because the greatest cold alway occurs in air having the least motion. Prof. Daniel says he has seen a difference of 30 degrees on th same night, between two thermometers, one place on an elevated situation and another in a sheltere valley. The shelter of walls may, therefore it woul appear, be so arranged as to prove injurious rathe than beneficial, by causing the air to stagnate and be come cold, as it does in sheltered valleys during th night.

The evaporation of water is so strongly productiv of cold, from the water requiring much heat to ex pand it, which it of course carries off into the air, tha in the hot climate of India, ice is, for the purposes o luxury actually procured in considerable quantity, b exposing unboiled pump water in broad shallow ear then pans placed on dry straw on calm cloudles nights, to the open sky.

It is from the rapid increase of cold by evaporatio that we account for the injury produced by waterin plants when a warm dry wind blows, or during brigh sunshine, which is popularly termed *scorching*, thoug it is not the heat that affects them, but the col caused by the water carrying off the heat as it arise in form of vapor into the air. Miller is undoubted ly wrong in supposing it to be occasioned by th sun's rays being brought to a focus, as in a burnin glass, by the small globules of water, for these glo bules, from their touching the plant, cannot brin the rays to a focus.

The injury caused by the melting of hoar-frost o frozen rain on plants arises from a similar cause, th carrying off a portion of heat from the plant in orde to render the frozen water fluid.

The amount of evaporation depends on the quan tity of moisture in the air, and the rapidity of its mo tion; or, in other words, on the velocity of the win Over the first the gardener has little or no contro but he can, by means of walls, palings, hedges, an other screens, obstruct or stop the current of th wind; or natural shelter may be found in uneve ground. Professor Daniell states that the same su face which, in a calm state of the air, would give o 100 parts of moisture, would yield 125 in a modera breeze, and 150 in a high wind. The dryness of th air in spring renders the effect most injurious to th tender shoots of this season, when it is desirable a shelter gardens from the easterly and norther winds in particular, by means of high walls plac not too far asunder.

I need scarcely allude to the extensive use whi is made of artificial heat in rearing the plants s warm climates, as well as in the various modes s forcing, for proof of its being of the first importan for every gardener to study the laws by which its d tribution is regulated, and the means by which th may be artificially economised in gardens both in the open ground and in plant houses.

INJURIOUS SUBSTANCES.

Plants are precisely similar to animals in respect to injuries caused by too much or too little food, as well as by what is of a deleterious or poisonous quality.

It is accordingly found that among the substances just mentioned as constituting the wholesome food of plants, they are injured by too much or too little water, and by too much or too little carbonic acid gas, and by too much or too little light or heat. Saussure found that when he confined plants in carbonic acid gas, they were as much injured as the consumptive patients whom Dr. Beddoes caused to breathe oxygen, which, in due quantity, is indispensable to health. Food, indeed, which is rich, concentrated, and without a due mixture of what is less rich, is injurious to both plants and animals; and, hence, plants will not thrive on distilled water largely mixed with carbonic acid gas without atmospheric air, or at least nitrogen to qualify it; any more than a man will thrive on nothing besides rich beef tea without bread or other qualifying substances: dogs have actually starved to death by feeding them on nothing but rich soup.

When, on the other hand, there is not sufficient water, every body knows that plants will wither, and when not enough is carbon, it is equally ascertained that they become pale or yellow; while a deficiency of nitrogen to cresses, cabbages, mustard, and turnips, will render them vapid and deficient in flavor.

Besides these causes of injury, there are certain substances which act even in smaller quantities as direct poisons. Arsenic, for example, will completely destroy the life of a plant, or of a seed, and M. Leuchs proved that the nine thousandth part of a grain was hurtful. Opium, likewise, will put the sensitive plant to sleep in half an hour, and laudanum will kill a kidney bean in one day. Cherry laurel water produces effects similar to arsenic. Iron, in the form of oxide, at least, when in any considerable quantity, is by no means favorable to vegetation, though iron finds its way in minute portions into most plants, and may be observed in some vegetable ashes in the form of the red oxide, or rust. It may be observed in the same form in soils of a reddish brown colour, many of which are far from barren; though they certainly do not owe their fertility to the iron, but are fertile in spite of it, owing to some other causes.

De Candolle seems to doubt iron being injurious, but the experiments of Dr. Home put this beyond question. One drachm of copperas, or sulphate of iron, in the rich mould of a garden, killed some plants of barley when an inch high; and he found most dark coloured infertile under soils, or *till*, owed their barrenness to iron. This result was confirmed by Sir H. Davy, who placed a primrose root in a solution of oxide of iron in vinegar, which soon acted as a poison and turned the leaves yellow; and he proved that the iron had entered the plant by testing the decoction with infusion of galls. Plants, as I have observed, which are grown by cottagers in old iron, or white iron pots, do not thrive, no doubt from the same cause, and it may be partly on the same account that granite soils are infertile.

Magnesia, it has also been found, is poisonous to plants; and hence, burnt lime from the limestone containing magnesia, as about Belfast, Durham, and some parts of Yorkshire, Derbyshire, Leicestershire, Shropshire and Somersetshire, when laid upon land, has been found to prove very injurious. It may be, that the small particles of the magnesia, which are insoluble in water, and do not readily attract carbonic acid gas, get into the minute suckers at the tips of the root-fibres and obstruct them, though no solid substance whatever can get into a plant; for it is found that when mixed with fat peat earth, magnesia does good rather than harm, because, in this case, it finds abundance of carbonic acid gas, by which it is converted into a carbonate of magnesia, that will partly dissolve in water by means of humic acid, and, consequently, supply plants with wholesome nutriment.

It must be evident, that besides having a due quantity of wholesome food provided for plants, this must be so placed as to be within reach of the suckers of their root fibres, since they cannot move about in search of it themselves; a subject, which, with some others may be treated of under the head of Paysics; a term now commonly used, and pretty generally understood, to comprehend explanation of facts from mechanical, as distinguished from chemical, principles.

The happiness of the human race, in this world, does not consist in our being devoid of passions, but in our learning to command them.—*Fr. Prov.*

Men of limited capacities generally condemn every thing that is above the level of their understandings. —*Rochefoucault.*

Perfect Subsoil Drainage and Deep Ploughing.

Every variety of good soil has a naturally dry, porous subsoil, being either a deep, friable, porous earth, sand, or gravel, or open rock; so that rain water will not rest on its surface, but readily pass through the stratum below.

The greatest injury which the land receives is from stagnant water on the surface, or between the soil and the subsoil.

Bad and worthless clay soil is generally that which is saturated by stagnant water.

If water be allowed to remain on good land, it will soon convert it into bad or worthless soil; a retentive subsoil has generally a soft or clayey surface, and is universally a bad and unproductive soil.

When the subsoil is retentive, the rain finds its way through the cultivated portions of the surface to the subsoil, and passes on slips between them to the furrows, keeping the cultivated portions of the soil wet and unfit for vegetation; but if the subsoil be porous, either naturally or artificially, it then goes directly through the subsoil or porous passage to the drains that are formed to draw off the redundant water.

It is the constant practice of the most scientific gardeners, when about to pot any plants, to put some broken tiles or gravel in the bottom of the pots to drain off the superfluous moisture from the plants to the hole in the bottom of the flower pots; and when they use a strongish or clay soil, instead of passing the soil through a sieve as formerly was the custom, they now chop it into small pieces, and thus give to strongish clay soils an artificial porousness which they naturally do not possess.

On examining the roots of plants growing in pots with soil thus prepared, we find the crevices between the broken pieces of earth full of roots, because they have not only a more easy passage where the soil is friable, in consequence of the lumps keeping the earth loose and porous between them, but here the drainage is most rapid and complete.

Land is not perfectly drained which, during the wettest weather, has any spots on it which the water rests upon, and gets stagnant for a short period; the rain should have a free course to sink down through the subsoil below the roots of plants, and then run off by the furrow-drains to the open ditches.

Complete subsoil drainage of the retentive soils can only be effected by having a drain in every furrow, or about one or at most two perches apart; and then by subsoil ploughing across the drains, and making an artificial porous stratum under the cultivated surface to within an inch or two of the stones in the drains, that the rain-water may fall through the surface and run in the subsoil to the drains. The effect produced on the crops of close retentive soils, after they have been perfectly drained and subsoil ploughed, is most astonishing.

The produce is so much increased that it will, in many instances, pay the expenses in a year or two; and wet soils, which seemed to be strong clay when wet, become friable and even light when completely subsoil-drained, are easily cultivated, and light enough for producing turnips to be fed off with sheep.

Perfect drainage and deep ploughing is the true principle of giving to the soil an increased fertility; by this means the plants are enabled readily to push their roots farther and deeper in search of food, which they obtain of a more healthy kind, than when the soil is imperfectly drained and ploughed shallow. All tenacious clay soils should be trenched or subsoil-ploughed once in every course of crops; or when they are in fallow; this practice not only gives to the roots of plants a greater scope to go in search of food in dry weather, but also furnishes a depth of porous substratum under the soil to draw off the superabundant moisture during continual wet weather, and transmits moisture to the roots of plants in continual drought.

The utility of trenching or subsoil-ploughing these soils, particularly such as have retentive subsoils, must be evident, for, if the toil on such a subsoil be well pulverized merely to the depth of the furrow slice, in continued wet weather it soon gets into a state unfit for vegetation; the water becomes stagnant, and all the soluble matter in the soil is either washed out, or locked up in the soil from being so thoroughly soaked as to exclude the air; and when it again becomes dry, it is as hard and solid a mass as bricks ready for the kiln.

In either of these states it is impossible for any plants to vegetate, the soil being at one time as soft and smooth as well tempered mortar, and at another almost as dry and hard as a stone.

But when the soil is artificially deepened by deep ploughing, and the subsoil is also made porous to much greater depth by the subsoil-plough, the rain gradually sinks down to the whole depth of the porous substratum, and from thence to the furrow drains; and in time of great drought, the deep moved ground will hold, by capillary attraction, a much greater supply of moisture for the nourishment of plants, thus draining off the abundant water during the heavy rains, and supplying the means for healthy vegetation at all times.

Complete or perfect drainage is the foundation of all improvements in husbandry; it should therefore be the first step which we take in attempting to improve or ameliorate the soil.

Land wet from springs should be drained by deep drains, so as to tap the porous stratum which contains the water at the lowest level if possible. But much the greatest part of what is called wet land, is so from its retentive subsoil, and the retentive adhesive nature of the soil, which so obstinately retains the rain that falls on it; so that the drying process is effected very slowly when compared with soil whose subsoil is either naturally or artificially porous. The working of such land is kept back, and is frequently not effected in proper time. Nature furnishes us with the principles which should direct all our operations in permanently improving soil or in cultivating it.

As we have seen that the richest and most productive soil has always a subsoil pervious to water, which carries it off as it falls by imbibing it or filtering it to a considerable depth below the active soil; so we ought artificially to make as complete a drainage of subsoils to produce the same effect by having drains from one to two perches apart to effect this, and by deep or subsoil ploughing across these drains to draw of the water to them which falls on the surface, so that the whole of the active soil may be always kept so dry as to be fit for the purposes of vegetation.

These drains must be sufficiently near each other to allow the redundant moisture to be speedily and effectually carried off by the artificial passage made at the bottom of the moved subsoil.

The distance of these drains must be regulated by the nature of the subsoil; if this be very close and impervious they should be only about one perch, but if it be to a certain degree pervious, they might be two perches apart.

Before we attempt perfectly to drain any land, we must first understand the principles of the system thoroughly, or we may only adopt certain general rules, without considering that the various kinds of subsoil will require particular modes to effect our object.

Mr. Smith of Deaneston first gave publicity to the mode of perfect drainage, and subsoil ploughing; he says, "The principle of the system is *the providing of frequent opportunities for the water rising from below, or falling on the surface, to pass freely and completely off*, and therefore the most appropriate appellation for it, seems to be, '*The frequent drain system.*'"—*Morton on Soils.*

Magnesian Lime Stone.—Almost every writer upon the use of lime in agriculture, has adopted the opinion of Tennant, that magnesian lime stone was hurtful to land; and although the practice in Pennsylvania had disproved the fact, the lime there used in agriculture abounding in magnesia, yet our own writers continue to persist in the error. "It is now asserted," says Parkes, "that lime and magnesia are both hurtful when employed in improper situations, or in excessive quantity, but that magnesia in itself is not essentially injurious."

Preserving meat without salt.—It is the practice in Thibet to prepare their meat by extreme cold.—The process is extremely simple. They kill, clean and strip the animal of his skin; he is then placed upon his legs in a commodious place, and left exposed to a free access of frosty air, until all the juices in his body are completely dried up, and the whole becomes one uniformed stiffened substance. It is then in a fit state for carriage to any part of Thibet, and for keeping to any season of the year. No salt is used in the preparation. I had supplies of this prepared meat during all the time I remained at Geshoo Soomboo, which had been cured in the preceding winter. It was perfectly sweet, and I was accustomed to eat heartily of it, *without further dressing*, and at length grew fond of it. It had not the appearance of being raw, but resembled in colour that which has been well boiled. It had been deprived of all ruddiness, by the intense cold.—*Turner's Embassy to Thibet.*

The salt mine of Wilitska, near Cracow, in Poland, is the largest in Europe, and has been constantly worked for more than 600 years. It is at the immense depth of 740 feet below the surface of the ground on which the town stands; and it is 1,100 feet wide, and 6,700 feet in length. The mine exhibits a spacious subterraneous plain, with lofty vaulted roofs, supported by columns of salt, which have been left standing for the purpose. Here a great number of lights are constantly burning, and the blaze of these reflected from every part of the mine, which appears bright and clear as crystal, or tinged with the most beautiful colours, presents a most enchanting prospect. In these mines 1,000 men are constantly employed. The passages contain altars and chapels, in which lights are continually kept burning before the images of the saints, and some of these galleries are capacious enough for a large church to be enclosed in one of them. That part of the mine which has been most excavated, and which appears like a vast plain, is interspersed with clusters of huts belonging to the miners and their families, many hundreds of whom are born and finish their lives in this subterraneous enclosure.

Near Cordova in Spain there is a mountain of rock salt 500 feet high, and three miles in circumference. —*Park's Chem. Essays.*

Young Men's Department.

Chemical Catechism—Chapter V.

OF EARTHS.

What are the principal characters of the earths?

The earths are incombustible bodies, and in general are unalterable in the fire. Till lately, they were thought to be unsusceptible of decomposition; they are insoluble in water, or nearly so, when combined with carbonic acid, and are of a specific gravity never exceeding five times that of water.

How many earths are there?

There are nine distinct earths known at present, viz. silica, alumina, zirconia, glucina, yttria, barytes, strontites, lime and magnesia.* The four I have enumerated last, are generally called alkaline earths.

Why are some of these earths called alkaline earths?

Barytes, strontites and lime, are called alkaline, because they agree with the alkalies in taste, causticity, solubility in water, and in their effect upon vegetable colors;† magnesia agrees with the alkalies in the latter property only.

What is the nature of silica, and what are its chief properties?

Silica, or pure flint, is a white, inodorous, and insipid earth; it is insoluble in water, and in every acid except the fluoric; it endures the strongest heat without alteration; but, when mixed with soda, or potash, becomes fusible in a strong fire into glass. Its specific gravity is 2.65.

In what state is silica found native?

Silica is found in almost all mineral substances, particularly in gravel, sand, quartz and flint, of which it forms nearly the whole substance.‡ It is also the chief ingredient of those rocks which constitute the most bulky materials of the solid parts of our globe.§

What are the chief uses of silica?

Silica is the the most durable article, in the state of gravel for the formation of roads; it is a necessary ingredient in earthen ware, porcelain and cements; is the basis of glass, and of all vitrious substances; and is an indispensable article in many of our chemical furnaces and utensils.

What is the use of silica in glass making?

Silica is the chief ingredient in glass. It is rendered fusible by a due mixture of alkali, which acts as a flux to the silica, and renders the whole transparent.

Are these the only articles necessary to form glass?

In Holland, and some other parts of Europe, glass is manufactured with sand and alkali only; but in England, [and in the United States,] flint glass is made by a mixture of red lead with those substances; which gives the glass great weight, and makes it more useful for all common purposes.||

What are the chief properties of alumina?

Alumina, or pure clay, is soft to the touch; adhesive to the tongue; emits a peculiar odor when moistened; forms a paste with water; has great affinity for coloring matter; will unite with most acids; and acquires great hardness, and contracts in the fire.* Like silica, it is soluble in caustic potash, or soda. Its specific gravity is 2.00.

In what state is alumina found native?

Alumina is distributed over the face of the earth in the form of clay, and from this circumstance, acquired the name of *argil;* it is found also in a state of crystalization in the sapphire, and other precious stones, and is united to the oxide of iron in the ochres. It obtained the name of alumina from being the base of salts called alum.

What are the chief uses to which alumina has been applied?

Alumina, on account of its aptitude for moulding into different forms, and its property of hardening in the fire, is employed in various ways, such as for making bricks, earthen ware, porcelain,† crucibles, &c. but the alumina which is made use of for these purposes, is always impure, as it is employed in the state of clay, and often as it is taken from the bowels of the earth, without any previous preparation whatsoever.

Is alumina employed in forming any direct chemical combinations?

Aluminous earth is employed for various purposes by the dyer and calico printer, especially in its combination with acetic acid, as a mordant for fixing madder reds, and some other colors, on calico; and upon the continent, it is artificially combined with sulphuric acid, in order to form alum; but we possess the compound, or alum slate, ready formed, in abundance.

Why do potters employ a mixture of alumina and silica for earthen ware?

In making earthen ware, a due proportion of both these earths are necessary; for, if alumina alone were used, the ware would not be sufficiently burnt without shrinking too much, and even cracking; and a great excess of silica would weaken the tenacity, and render the ware brittle.

What is the nature of that very hard species of pottery, called stone-ware?

Stone-ware, like other pottery, is chiefly composed of alumina and silica; but a certain quantity of old pottery, finely ground, is generally introduced into its composition. The difference, however, between this and common earthen ware, chiefly consists in the burning and glazing; stone-ware being always submitted to a much higher degree of heat, and in its being glazed with muriate of soda, (common salt,) instead of the oxide of lead. On account of the superior strength of stone-ware, its very compact texture, and the wholesome nature of its glaze, it is greatly to be wished that its use be considerably extended, and that every article for culinary purposes were to be manufactured from it.

What constitutes the difference between earthen ware and porcelain?

Porcelain is not esteemed good, unless it be very compact, quite white and semi-transparent;‡ indeed, it is chiefly the last quality that constitutes the principal difference, for *earthen* ware is always opaque.

---

* To a cursory observer, the earth appears indefinitely diversified; so much so, that he would probably think the different kinds innumerable. However, notwithstanding the varied appearance of the earth under our feet, of that of the furrows of the field, and of the mountainous parts of the world, whose diversified strata present to our view substances of every texture and of every shade, the whole is composed of only nine primitive earths; and as three of these occur but seldom, the *variety* which is produced by the other *six*, becomes the more remarkable. This may fairly be adduced as one instance of the infinite skill of the Deity, as it "bespeaks an artist, master of his work, acquainted with his materials."

To give a still greater variety to the works of nature, these earths are endowed with an affinity for acids and metallic oxides, whence arise the spars and gems, and precious stones, of every color and every species.

"Th' unfruitful rock itself, impregnated by Thee,
In dark retirement forms the lucid stone."

† Barytes, strontites, lime and magnesia, are found in nature always combined with acids. None of the combinations are very hard, as either of them may be scratched with a knife. The acids which are found by nature united with these alkaline earths, are generally the carbonic, (as in lime,) sulphuric, (as in gypsum,) the fluoric, (as in Derbyshire spar,) the boracic and the phosphoric.

‡ In 1760, the Emperor of Germany caused, by permission of the Grand Turk, one of the timbers which supported Trajan's bridge over the Danube, below Belgrade, to be taken up and examined. The outer part of this bridge, to the depth of half an inch, was found to be converted to an *agate;* the inner parts were slightly petrified, and the central were still wood. The agate is a mineral, composed of silica and alumina, but chiefly silica. These timbers had been buried in the waters of the Danube nearly 2,000 years.

§ A granite mountain, about thirty miles from the Cape of Good Hope, called the Pearl Diamond, rises out of the ground, to the height of four hundred feet, being half a mile in circumference, and formed of a single block of granite. Silica also constitutes two-thirds of the asbestos, so valued by the ancients for wrapping up the dead before they were committed to the funeral pile. They discovered the method of drawing the fibres of the mineral into thread, and afterwards weaving it into cloth. In consequence of its incombustibility, it preserved the ashes of the body from mixing with those of the wood, upon which it was laid to be burnt. [Samples of paper, indestructable by fire, were presented to the Conductor, some thirty years ago, by Mr. Benjamin, who then owned and managed a paper mill at Catskill.]

|| The common bottle glass is made with a large portion of the ashes of vegetables, or soap-boiler's waste ashes, instead of pure alkali. The portion of iron, which is generally found in vegetable substances, gives it the green colour

* Common clay is a mixture of alumina and silica. Fuller's earth is alumina combined with very fine silica. It is owing to the affinity which alumina has for greasy substances, that this article is so useful in scouring cloth. Hence pipe-clay is frequently used for the same purpose.

† The beautiful colors which are seen upon porcelain and earthen ware, are given by metallic oxides. Purple is given by gold; red by the oxide of iron; yellow by the oxide of silver; green by copper; blue by cobalt; and violet by manganese.

‡ Porcelain is an artificial compound of great durability. There is an octagon tower at Nankin, in China, called the porcelain tower, which is entirely covered with the most beautiful china. It is a building of nine stories, nearly 300 feet high, and each story decreases in breadth as it rises in height. It retains its beauty, though exposed to the action of the sun and weather for more than 400 years.

He that would govern his actions by the laws of virtue, must regulate his thoughts by those of reason; he must keep guilt from the recesses of his heart, and remember that the pleasures of fancy, and the emotions of desire, are more dangerous as they are more hidden, since they escape the awe of observation, and operate equally in every situation, without the concurrence of external opportunities.—*S. Johnson.*

Nature is said to be a *mother* to some people, and a *step-dame* to others; but the real truth is, that providence is kind to all alike, and it is industry only that makes a difference between nations and individuals; for those who contemplate her gifts, and study how to make use of them, very rarely fail of finding their pains rewarded, even beyond their expections.—*Dr. Campbell.*

Choice Scraps.

To have become possessed of riches, is, to many, not the end of their miseries, but merely a change in them; the fault is not, however, in the riches, but in the mind.—*Seneca.*

There are many men who appear struggling against adversity, and yet are happy; but yet more, who, although abounding in wealth, are miserable.—*Tacitus.*

I consider that man to be undone who is insensible to shame.—*Plaut.*

Such is the affinity for water, in some earths and alkalies, that pure allumine (clay) will retain a tenth of its weight of that fluid, according to Saussure, even though it be submitted to a heat that will fuse iron. And potash, according to Darcet, submitted to a red heat, retains 13 per cent of water, and soda nearly 19 per cent.

For lineage, ancestry, and all other things which we have not ourselves acquired, can scarcely be called our own.—*Ovid.* Every man should feel more pride in acquisitions obtained by his *own* merit, than in honorary distinctions earned by his ancestors.

Nature has placed the means of happiness within every man's reach, if we did but make a proper use of her gifts.—*Claud.* It is from our abuse of those things which Providence has bestowed as blessings, that most of the calamities arise which affect mankind.

Avarice, (as also ambition and other evil passions,) when it has once passed the proper limits, knows no bounds.—*Seneca.* New gratifications only excite new desires.

Nothing flies so swiftly as calumny—nothing is so easily propagated—nothing is more readily received—nothing is more widely disseminated.—*Cicero.*

"On eagle's wings immortal scandals fly."

It is not that which is commonly considered as a woman's decory, that I estimate as such, but her chastity, modesty and controlable passions.—*Plaut.*

FROM THE STEAM PRESS OF
PACKARD, VAN BENTHUYSEN & Co.

THE CULTIVATOR:

A MONTHLY PUBLICATION, DEVOTED TO AGRICULTURE.

I KNOW OF NO PURSUIT IN WHICH MORE REAL AND IMPORTANT SERVICES CAN BE RENDERED TO ANY COUNTRY, THAN BY IMPROVING ITS AGRICULTURE.—*Wash.*

VOL. V. NO. 3, WASHINGTON-ST. ALBANY, N. Y. NOVEMBER, 1838. No. 9.

Conducted by J. BUEL, of Albany.

TERMS.—ONE DOLLAR per annum, to be paid in advance. Subscriptions to commence with a volume.

Special Agents.—L. & R. HILL, Richmond, Va.; BELL & ENTWISLE, Alexandria, D. C.; GIDEON B. SMITH, Baltimore, Md.; JUDAH DOBSON, bookseller, D. LANDRETH, and M. S. POWELL, seedsmen, Philadelphia; ISRAEL POST, bookseller, 88 Bowery, ALEX. SMITH, seedsman, P. WAKEMAN, office of the American Institute, Broadway, N. York; HOVEY & Co. Merchants' Row, Boston; ALEX. WALSH, Lansingburgh, and WM. THORBURN, Albany, gratuitous agents. For general list of agents see No. 12, vol. iv.

The Cultivator is subject to common newspaper postage.

☞ Price of the published volumes, 50 cents per vol. stitched—the four volumes bound together, $2.75—bound in two volumes, $3—the four vols bound each separate, $3.25.

THE CULTIVATOR.

TO IMPROVE THE SOIL AND THE MIND.

We invite the reader's attention to our article headed *Common School Libraries*, as affording an outline of *one* of the particular objects of the society, and as exhibiting the terms of membership; and we invite our brethren of the press, to commend this matter to the notice of their readers, as one fraught with incalculable benefits to our common country.

Morus Multicaulis Speculation.

If our produce in silk is likely to increase in any thing like the increased demand for this species of the mulberry, and its rapid multiplication, we shall be able, in a few years, to clothe our entire female population in silken fabrics, and to export largely in the bargain. But the demand seems to originate from a hope of making money by speculating in the *buds*, or *trees*, rather than in the *silk* which they are to produce. Individuals have for some time been traversing the several states, from Canada to Florida, buying up these trees, and the prices have kept advancing till they have reached an extravagance beyond reason, and almost beyond credibility. The Farmers' Register informs us, that Thomas Hicks, of Virginia, laid out $345, in 1836 and 1837, for trees of the multicaulis, and that he has recently sold from their product, 20,000 trees, at 25 cents each, retaining 10,000 for his own use—thus realizing a profit of nearly $7,500 upon the outlay. In ten days, the seller might have received $1000 more for those disposed of. This was in September. In October, the fever of speculation had reached, if not its climax, at least a dangerous height to buyers: for the U. S. Gazette informs us, that at a great auction sale of these trees, at Baltimore, on the 4th inst. 120,000 of them were sold, "at prices varying from 20 to 22 cents per foot, measuring to the utmost extremity, and counting the roots also. This amounts to $1.21 for each tree of five feet high." At a sale at Germantown the prices exceeded 20 cents per foot. At Burlington, N. J. a sale of 2430 was made by Mr. Greenmere, for $2500, and another of 1000 selected trees for $2000, being two dollars each. If this is not a "*Robin's alive*" business, in which some one will get sorely "*saddle-backed*," we are greatly mistaken.

There is no tree more rapidly multiplied, probably, than the morus multicaulis. Every uninjured bud will produce a plant in a summer. The practice is, among proficients in the art of propagating, to take off every branch and the top, or to take up the entire young plants, in the autumn—to bury them in the ground, or put them in a cellar during winter, and to plant them in the spring, either in cuttings of one or two eyes, or by covering the branch or young plant, laid horizontally in a furrow, with an inch or two of earth. Almost every bud will grow from two to four feet the first season, and ultimately become a tree. This will explain to the reader, why select trees, abounding in branches and buds, sold for two dollars at Burlington. They were cheap, *if* the prices can be kept up another year.

In regard to the culture of this mulberry in our latitude, we have only to repeat the opinion we have often expressed, that the *tree* will not stand our winters, except, perhaps, upon a poor dry soil, when the growth ceases, and the wood hardens, before the occurrence of severe frosts. Indeed this is now virtually conceded by the growers; for we believe it is the general practice to secure seedlings in the cellar, or to bury them in the ground, and to cut down the trees, cover the stumps, and secure the tops and branches for propagation. Cutting down at autumn is recommended as the best mode of increasing the foliage, and as facilitating the gathering of the leaves—as many sprouts spring from the stump in the spring, and the leaves of which may be gathered without climbing.

That the silk business will ultimately prosper among us, we have no doubt; but that the multicaulis is to supersede all other species of the mulberry, or that it possesses very remarkable properties not common to the family, we must be permitted to entertain doubts. Gen. Tallmadge, who visited the silk establishments of Italy, and was minute in his inquiries, tells us that the European black mulberry had a preference there. In France the white mulberry, it is alleged, produces the best silk. We have seen beautiful fabrics from our native red species. While those who have seen, at Constantinople, the silks produced from the Brussa, affirm that they exceed all others for lusture and value. Men are prone to recommend that which they wish to sell. In our mind, it matters little what species of mulberry we cultivate, provided it is hardy enough for the climate. If any kind is well managed *by household industry*, they will, in our opinion, become a certain source of profit to the owner.

Experiment in Harvesting Corn.

In our last November No. we gave the result of an experiment in harvesting corn, going to show, that it is better to cut it up than to top it. We now give the result of another experiment of the same kind.

In the first week of September, we went with two neighbors into our cornfield, where our men were cutting up corn, and caused 36 hills to be cut up, where we found them at work, which was of the fair average quality of the field, and stooked separately; adjoining which 36 hills were topped, in the usual way; and a third parcel of 36 hills, immediately adjoining the last, was left to ripen upon the entire stock. On the 23d September we proceeded to pick, husk and weigh the corn on the several parcels. The result was as follows:

No. 1, cut up,	had 126 ears,	which weighed	56½ lbs.
No. 2, topped,	“ 127	“	52 lbs. 2 oz.
No. 3, standing,	“ 125	“	52 lbs. 10 oz.

We found on trial, the same evening, that it required 78 lbs. of ears to give a bushel of shelled corn. The field was planted at exactly three feet between the rows, and at about two feet four inches in the rows; but assuming that the distance was three by two and a half feet, it would give to the acre 5,808 hills—and there probably was not 20 hills deficient in five acres. Upon these data the product on an acre, under the different modes of harvesting, would be as follows, omitting fractions:

No. 1	would give	9,274 lbs.	or	119 bushels.
No. 2	“	8,409½	“	108 “
No. 3	“	8,490	“	109 “

Although the parcels selected were supposed to be similar, it was perceived, after the corn was gathered, that an apple tree, giving a shade 6 to 7 feet broad, stood in No. 3—the whole field being a young orchard—which undoubtedly had an influence in lessening the product of that parcel—as it might reasonably have been expected to have exceeded that of No. 1.

In regard to the condition of the grain, of the different parcels, that of No. 1, which had been cut up and stooked, was unquestionably best: it was dry, sound and bright; while much of Nos. 2 and 3, which had been topped, or left standing entire, had fallen upon the ground, was wet or mouldy, and some of it had actually grown. The difference in the fodder was still more palpably in favor of No. 1—it evidently exceeding in value either of the other parcels more than one half.

Our neighbors, C. N. Bement and Sidney Chapin, were present, and assisted, in the cutting up, topping, picking, husking, weighing and examining, the several parcels, and have authorized us to say that they fully concur in the preceding statement.

In our experiment of last year, the loss in topping, over cutting up, was found to be about six bushels; in the above detailed experiment it appears to be eleven bushels on the acre. It will also be observed, on referring to our former experiment, that the number of ears, and the product, is less this than it was last year. This has been caused by the drought. None of the succors produced ears this year, though many produced them last year.

This experiment confirms us in the opinion we have long entertained, that there is a prodigious waste, both in corn and forage, and we insist in labor also, in the still common practice of topping corn. And we again beg, that those who remain incredulous in the matter, will make the experiment, as we have repeatedly done, and satisfy themselves. Say there are 300,000 acres of corn cultivated in this state, and that the loss by topping is only five bushels to the acre, the aggregate loss would amount to 1,500,000 bushels, equal at least in value to one million of dollars annually, to say nothing of the loss in labor and forage.

The *cause* of the topped corn having produced less than that which was cut up, although often stated, is here repeated: the topped corn was deprived of its elaborating organs—its lungs—the leaves above the grain, and of course received no farther accession of growth, or but very little; while the corn cut up retained these organs, which continued to send down nourishment to the grain for some days through its green succulent stocks. Any farmer may satisfy himself readily that leaves are indispensable to growth, by a simple and easy experiment:—let him pluck all the leaves from a fruit-bearing branch of the apple, plum, or other fruit tree, at any stage of growth of the fruit—and he will find that the fruit on such limb will neither grow nor mature its flavor where there are no leaves—though it may change its colour.

Rohan Potato.

A few tubers of this potato were introduced from France, in 1836. We have cultivated them two seasons, and feel justified in recommending them as a valuable acquisition in our husbandry—

First, because their quality, for the table, will justify it. If not superior, they are good. The flesh is yellow, solid, and of good flavor.

Secondly—because they admit of a great economy in seed—two eyes sufficing (and many of the tubers have thirty to forty eyes,) to plant a hill, and three or four bushels to plant an acre of ground.

Thirdly—because they require comparatively little labor in harvesting—a man being able to dig thrice as many of them in a day as of ordinary kinds. The tubers are very large, one hundred and ten, of the largest of our crop, completely filling a flour barrel. Twenty-seven bushels were dug in our presence in one hour, the tops being pulled, by one man, at moderate labor.

Fourthly—because they yield an abundant crop. From 85 rods of ground we gathered 175 bushels, while our common cultivated kinds did not give us half a crop. One case has been stated to us, of a single potato producing a bushel, and another of its having produced a barrel, at harvest.

This potato sends out laterals from the main stem, which grow to great length; and the roots which feed it, strike deep, are numerous and strong. Hence the ground in which they are to be planted, should be ploughed deep, and the hills should be placed widely apart, that the soil may acquire solar heat. We ought further to remark, that they should be planted early in our climate, as early as the ground is sufficiently warmed for their reception, as they seem to require the whole season to grow their large tubers and mature the crop.

The principal growers of this potato, we believe, are J. A. Thompson, Esq. of Catskill, who was one of the first to introduce them into our country, and C. N. Bement. It may supersede inquiry to state also, that the price at which the growers hold them, is $9 the barrel, or $3 the bushel. Our crop has been disposed of. They are sold by the Messrs. Thorburns, at Albany and New-York.

The product of this potato, with Mr. Harger, (see correspondence) was 144 lbs. for 13 ounces of seed planted; and we are informed by a gentleman from New-Haven, that some of his tubers were sold at the horticultural fair in that city at one dollar each!

Agricultural Societies.

A new agricultural society has been recently formed in the north part of Otsego, which held its first exhibition at Cherry Valley, on the 17th inst. An address was delivered on the occasion by Mr. Senator Beardsley. The exhibition of farm stock, we understand, was uncommonly fine, and embraced choice animals of the improved breeds of neat cattle, sheep and swine, which occupied seventy pens, besides many bulls, and other animals that were tied to posts, &c. Otsego is destined to be one of our best districts for cattle and sheep husbandry; and perhaps no county can even now boast of more fine animals, than have been imported, collected and raised by her enterprising breeders. A society already existed at Butternuts and its vicintity.

The *Fulton County Agricultural Society* was organized, at Johnstown, on the 18th October. This county is also well adapted to cattle and sheep husbandry, and some fine animals have been already introduced there. The dairy business is particularly engaging the attention of the western towns. Great quantities of butter and cheese are annually produced; the business is extending, and makes liberal returns to those engaged in it. The southern border of this county, particularly the district about Johnstown, has long been celebrated for its fertility. It is well calculated for alternate and mixed husbandry. The new society, if conducted upon liberal and wise principles, with a view to enlighten, stimulate and benefit all, will not fail to produce highly beneficial effects.—The products, in the glove and mitten business, are stated to amount in value to a quarter million dollars annually, in that county.

The *English Agricultural Society*—a national institution—was organized in London in June, under Earl Spencer as president, twelve trustees and eleven vice-presidents, all belonging to the nobility or to parliament. We mention this latter circumstance merely to show, that the first men in the British empire are the ardent active advocates of agricultural improvement; and are devoting their time and means to its advancement;—and in the hope, too, that their example may have a benign influence upon the great men of our country, in inducing them to become active and liberal promoters of improvement in this great branch of national industry, and primary source of national wealth. They may be assured that they can hardly render, in any other way, a more enduring service to their country, or to its civil institutions.

Among the avowed objects of this society, are the following, which we copy for the particular information of our statesmen, and for the benefit of our readers generally, as indicating some of the prominent means of improvement. These objects are,

"1. To embody such information contained in agricultural publications, and in other scientific works, as has been proved by practical experience to be useful to the cultivators of the soil.

"2. To correspond with agricultural, horticultural, and other scientific societies, at home and abroad, and to select from such correspondence, all information which, according to the opinion of the society, is likely to lead to practical benefit in the cultivation of the soil.

"3. To repay any occupier of land, or other person who shall undertake, at the request of the society, to try any experiment how far such information leads to useful results in practice, any loss that he may incur by so doing.

"4. To encourage men of science in the improvement of agricultural implements, the construction of farm buildings and cottages, the application of chemistry to the general purposes of agriculture, the destruction of insects injurious to vegetable life, and the eradication of weeds.

"5. To promote the discovery of new varieties of grain, and other vegetables useful to man, or for the food of domestic animals.

"6. To collect information with regard to the management of woods, plantations and fences, and on every other subject connected with rural improvement.

"7. *To take measures to improve the education of those who depend upon the cultivation of the soil for their support.**

"8. To take measures for improving the veterinary art, as applied to cattle, sheep and pigs.

"9. By the distribution of prizes, and by other means, to encourage the best mode of farm cultivation, and the breeds of live stock."

Among the rules of the society, it is declared to be a fundamental one, that no questions of a political tendency shall be discussed at its meetings.

Among the prizes for essays, is one of 50 sovereigns=to $220 "for the best account of the improvements which have taken place in the agriculture of Scotland since the formation of the Highland Society."

Premiums of ten and twenty sovereigns are also offered for the best essays, verified by practice, upon the following subjects:

"1. Best mode of keeping roots;
2. Subsoil or trench ploughing;
3. Transposition and admixture of soils;
4. Insects prejudicial to plants;
5. The black caterpillar which destroys turnips;
6. Application of mechanical power;
7. Two horse ploughs;
8. Spring food—corn—grasses—vetches;
9. Rotation of crops;
10. Best mode of analyzing soils;
11. Irrigation;
12. Plantations;
13. Underwood;
14. Varieties of grain:
15 Economical keep of farm horses;
16. Improved rural economy abroad;
17. Stall feeding on the continent;
18. On the diseases of plants."

This society embraces 186 governors, that is, subscribers who pay £5, equal to $22.20, annually.

All of these matters, it will be readily seen, have a strong bearing upon improvement in agriculture,—they aim at substantial and permanent improvement—and will afford useful suggestions, to our agricultural societies, in the bestowment of their awards.

Agricultural Chemistry.

The importance of this science to profitable farming, becomes particularly apparent, where mineral, bone and other manures are employed. At the organization of the English Agricultural Society, in June, this matter was particularly alluded to by J. Bennet, Esq. M. P. "It was well known," he said, "that on some lands lime was useful, whilst on others it was detrimental; bones were advantageously employed on one class of lands, and were hurtful on others; and other chemical manures which were applied on some soils were injurious to others. The adaptation of manures to soils [and to crops] was very important, and could not be better illustrated than by the plan proposed [indicating, by different colours, upon geological maps, the different compositions of soil.] He hoped the society would be in possession of a chemical apparatus, with an able chemist that might be able to analyze the soils which might be sent them, and point out these adaptations. Artificial manures were becoming of more importance, and he doubted not they would continue more to flourish and be adopted. There was a necessity that every science connected with agriculture should be more fully developed, and this development would be effectually accomplished through the medium of the society."

We have vast resources of fertility in our lime, gypsum, ashes, peat earth, poudrette, bones, salt, &c. but the great difficulty is, we do not know where to apply them, from not possessing a chemical knowledge of our soils; and the frequent failures which happen from misapplication, prevent their being applied in a thousand cases where they would produce the best effects. What wonders have been wrought, in the woollen and cotton business, in a few years, by the aids of chemical science! And is there not a strong probability that as great benefits may yet result to agriculture from this wonder-working science?

Let us not be misapprehended: we mean chemistry in the *field*—not in the *closet*—practically tested and illustrated on the *farm*, by its teachers—and not alone in the *laboratory*. The one is mere theory—the other theory confirmed and rendered certain by practice. In the manufacturing arts, it is the chemist himself who applies the science to the art—who teaches the *application*, as well as the *principles* of science—the *hands* as well as the *head* of the pupil. And it must be so, we apprehend, in agriculture, before we can expect to derive great benefits from its aid. It is to *schools* which combine the science and practice, where the principles can be demonstrated and taught in the field, and by men specially devoted to the improvement of our husbandry, that we must look for the important aids which chemistry is capable, and we believe destined, to give to the parent art.

The philosopher may build up theories, and establish principles, which he may deem beneficial to husbandry,—and others may implicitly adopt his opinions—and neither of them may ever test them upon the broad theatre where they are intended to operate—and yet, on trial they may prove illusory and unsound. The theory of Tennant, that magnesian lime is prejudicial in agriculture, is a notable instance of error being thus perpetuated. His opinion has been implicitly adopted by most of the subsequent writers upon this subject; and, if it has not done much mischief, it has certainly prevented much good. The limestones of Pennslyvania abound in magnesia, and yet they have been found highly beneficial to her agriculture. And we have before us, in the Farmers' Magazine, a palpable disproof of the correctness of Tennant's hypothesis. The writer of the article alluded to has been in the constant use of the very magnesian lime, in Leicestershire, which Tennant had pronounced hurtful to agriculture, and has applied it, in some cases, to the extent of 400 bushels to the acre, and with encouraging success. The prejudice excited against this lime by the chemist, had prevented the farmers, at whose doors it lay, from using it; and they had been in the habit of obtaining their lime from a distance at considerable expense, till Tennant's theory became exploded by the demonstrative practice of the writer. We repeat, that we fear agriculture will not profit, as it may and ought to do, from chemical science, until it is coupled, in schools of instruction, with the practical application of its principles to the soil.

Agricultural Improvement.

The best way to show what *can* be done, is to show what *has* been done—and the strongest incentives to improvement are the comforts and enjoyments which they confer. Individual illustrations, both of improvements in husbandry, and of the blessings they bring in their train, are to be found in almost every district, but the lesson becomes more useful and impressive when we can extend it to a district of country. A case of this kind is recorded in the Farmers' Magazine for August. It is a contrast of the rural condition of Ayrshire, a district of Scotland, in 1793 and in 1838. At the former period, its husbandry was in the most wretched state, as bad as our worst managed districts—now it is one of the best managed and most productive in Great Britain. All this change has been effected in less than fifty years. We copy it in the hope that its perusal will do good, by stimulating our readers in the work of improvement.

"Col. Fullarton drew, in 1793, a most deplorable picture of the wretchedness, ignorance and apathy in which the farmers were sunk, up to the middle of the last century. The land was neither cleaned nor drained. Four horses were now and then yoked to the clumsy old fashioned plough, and frequently three horses with drivers. When the plough was drawn with a pair of horses, it always required two men to manage it—one man to hold the plough, the other to drive the horses. But what a contrast does the present state of this country afford to the miserable condition of farming in Ayreshire, during the last century? Fields, in many places, completely tile drained, and subsoil ploughed,—in others, similar improvements going forward—large tile-kilns erected upon nearly every estate, to promote drainage and productiveness of agriculture—good fences, chiefly of quick-set thorns—ploughs of the best construction, drawn by active, well bred, and fed horses, and guided by skilful ploughmen—agricultural societies to collect together those engaged in farming pursuits—to reward merit—to diffuse useful knowledge, on all matters connected with rural economy: and, above all, an intelligent local press, to glean from all quarters, for circulation, what is worthy the attention of the farmer to know, how to improve the management of his farm—comfortable neat farm buildings, and other conveniences—the finest breed of dairy cows in their island. These particulars—these important alterations and improvement,—mark out Ayrshire in 1838, as mightily advanced in the high scale of agriculture, since Col. Fullarton described it in 1793."

The Robinson Fund.

The Editor of the Franklin Farmer, B. Stevens, offers one hundred dollars,—and the publisher of the same paper, Fred. Pettit, one hundred dollars, to the *Robinson Fund*, to be awarded as premiums to the writers of the best agricultural school books. See Mr. Robinson's propositions in our October number. So the fund now consists of eight lots of land, whose assessed value is $440—and $320 from the establishments of the Franklin Farmer and Cultivator—Total, $760. Who will direct us to add his name to the list of contributors, and for what amount?

Governmental Patronage to Agriculture.

The (London) Farmers' Magazine, for August, gives, as its leading article, and with commendatory remarks, the outlines of the bill reported by our friend Allen, in our last House of Assembly, "to encourage agriculture." There is only one mistake about the matter. That journal states that the bill had become a *law*—when the fact is, it not only did *not* become a law—but its provisions were not even discussed—except by one house, an hour or two, in evening sessions. We hope the next legislature will amend the record, and endorse *passed* upon what the London editor considers already so.

The Turnip Fly,

Has been uncommonly destructive this year to the ruta baga crop. It seems now to be confidently affirmed, in some of the European agricultural journals, that sulphur, or brimestone, may be effectually employed as a preventive. One mode of using it is, slightly to moisten the seed and roll it in sulphur, previous to sowing. The other, to keep the seed for some time in sulphur, and to sow the sulphur with the seed. It is affirmed, that the young plants in this way become so strongly inpregnated with the sulphur, that the fly will not touch them. Sulphur is so extremely subtile, that it is known to diffuse itself, in a very short time, through the vegetable, as well as the animal system; and it is known to be obnoxious or destructive to the whole race of insects. The turnip seed imbibes it, and imparts it, with the sap, to the young plumule, or stem. Although the prescription is now out of season, it should be laid by for trial at the sowing season.

A Great Sale of Imported Durham Short Horns,

Is advertised to take place at Powelton, near Philadelphia, on the 5th Nov. The cattle are of the stock of Mr. Whitaker, one of the most eninent breeders in Britain.

---

*We would add, as applicable to our own condition—"*and upon whom the state must ever depend for the perpetuity of its civil and religious freedom.*"

The American Society for the Diffusion of Useful Knowledge,

Was organized in October, 1836, and now comprises, we believe, gentlemen in every state, distinguished for literature, science and public usefulness. Its objects, as its title purports, is the diffusion of useful knowledge among the great body of the American people, in the cheapest, purest and most efficient form. Such an object is worthy of the philanthropist and the patriot. It is in consonance with our highest duties as men, and as *free* men. It invokes the best feelings of our nature, and promises, in its results, the enlargement of individual enjoyment, (for *self*, some how or other, will always be the prompting motive to action,) BY PROMOTING THE PROSPERITY AND HAPPINESS OF ALL AROUND US.

This society seems modelled on the plan of a similar one in Great-Britain, of which Chancellor Brougham is the distinguished head, and which has been eminently useful, not only to the country where it exists, but to the civilized world, in the publications which it has issued from the press, relating to all the useful branches of knowledge, and which have had a circulation unprecedented in the annals of printing. It is by carefully selecting for the press, that public taste and public morals are improved, and general improvement promoted. It is by means of heavy editions, that works of merit are afforded at a third or a quarter of the ordinary cost, and that they consequently obtain a more general circulation, and a more benign influence upon national manners and character. We are indebted to the British society for a knowledge of many of the improvements of the day, in science and in the arts of labor. The farmer is indebted to them for the many valuable extracts, which appear in our agricultural journals, from their "Farmers' Series," on the various branches of husbandry; and all classes of readers are indebted to them for their Libraries of Useful and Entertaining Knowledge, Journal of Education, maps, treatises on Political Economy—for their Penny Magazine, Encyclopædia, &c. Their labors have produced a new era in intellectual improvement. The American Society, if properly supported by our citizens, cannot fail of doing infinite good to our country, and of conferring lasting benefits upon posterity.

Common School Libraries.

We insert to-day, a communication from "*A Westchester Farmer,*" in answer to our remarks in the August No. of the Cultivator, on the subject of common school libraries. Although it does not alter our opinion as to the books which ought to constitute the *basis* of a common school, or rural library, it serves to explain why works upon rural affairs have not formed a larger portion of the first class, which has been recommended to the districts.

From the documents accompanying the communication, we find that it is in contemplation, to publish a series of volumes upon agriculture—to consist of treatises "on the nature and properties of soils; the products of the vegetable kingdom, the culture and use of all trees, plants and vegetables, usually cultivated for use or profit; on the history, nature and management of the different domestic animals and their productions; in short, on all subjects connected with the pursuits of husbandry, designed to furnish the sons of the farmer, in a country destined to such high agricultural interests as ours, the best facilities for acquiring all necessary and desirable knowledge connected with their employments, their interests and their happiness." And the synopsis of the contemplated library embraces the following enumerated subjects which relate to husbandry: Soil, its varieties and culture; the vegetable kingdom; timber and wood; vegetables for the food of man; do. of animals; orcharding; horticulture; vegetable physiology; chemical functions of vegetables; management of live stock; the horse, cattle, sheep, poultry; the honey bee and silk-worm; animal mechanics; chemical functions of animals; agricultural economy; household economy and the dairy.

These works upon agriculture, together with others which are promised upon the arts, and upon physical, intellectual, moral and political science, will, when the whole is completed, form an invaluable library, which cannot fail of producing, in a few years, the most benign effects, upon the industrial, moral and social habits of every school district into which it shall be introduced.

Under the view of the subject which these facts present, we feel no hesitation in expressing a hope, that every school district will avail itself of the opportunity which now presents, of laying the foundation of a work of usefulness, which, after benefiting the present generation, cannot fail of imparting lasting advantages to posterity. The books now published consist of 50 vols. averaging 250 pages each, of uniform size and binding, boxed in sets, the box serving as a book case, with lock and key—and the whole may be purchased, including the book case, at *twenty dollars.*

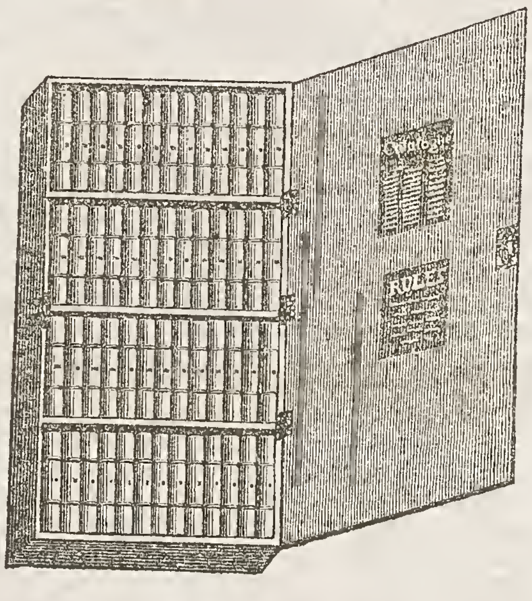
The 4th section of the act of last session, "to appropriate the income of the United States deposite fund to the purposes of education and the diffusion of knowledge," is as follows:

"The sum of fifty-five thousand dollars shall at the same time be annually distributed to the support of common schools, in like manner and upon like conditions as the school moneys are now or shall hereafter be distributed, *except that the trustees of the several districts* SHALL appropriate the sum received TO THE PURCHASE OF A DISTRICT LIBRARY, *for the term of three years;* and after that time for a library, or for the payment of teachers' wages, in the discretion of the inhabitants of the districts."

The law is therefore mandatory upon the school districts, for three years, provided the districts raise an equal sum for this purpose. After three years it is left discretionary with the districts whether the amount shall be applied to make additions to a library, or to the payment of teachers' wages. The proportion of this appropriation to each district will be about half the amount received last year from the common school fund.

FORM OF THE BOOK CASE.

[Fig. No. 55.]



It is a flat box, two feet long, one foot wide and six inches deep, divided by partitions which become shelves, when the box is placed upright, into seven compartments. The cover is attached by hinges, so as to become a door when the box is opened.

We cannot employ a page of the Cultivator more usefully, than by giving entire, the

"*Prospectus of the American Library for Schools and Families.*"

"The American Society for the Diffusion of Useful Knowledge proposed from the commencement, to devote very early attention to the publication of a series of works, on the more important branches of popular knowledge, to be prepared and issued in a style and manner, suited to the purposes of a School Library. The primary object was, to have them placed as extensively as possible, in the common schools of the country, that they may be loaned to the children, and circulated through them among all the families of the districts. Some of the considerations which have led the society to attach special importance to this plan, are the following:

"1. The social, circulating library is unquestionably the most economical and efficient mode of supplying the means of knowledge, to the large mass of young persons between the ages of ten and twenty, in the common school districts, throughout the country, now almost wholly unprovided with books of general information.

"2. This class of persons are at a period of life, in which the means of knowledge are of the highest interest and value. In youth, the powers of the mind are all in active exercise. Curiosity is awake; memory is faithful; the attention, not yet distracted by the engrossing eares of active life, gives itself wholly to its work. There is an ardor in the thirst for knowledge, which shows itself in the intense eagerness to *hear* and *know;* and many would seek constant gratification from books, if books could be obtained, of a character adapted to their taste and age. This period is the best time in life, for storing the mind with knowledge, and almost the only time to acquire a *taste* for its attainment in future years.

"3. Such a library will be the means of great advantage and improvement to the schools with which they are connected. It will, in fact, add a new department to the system of education, the influence of which will extend to the whole population. It will concentrate interest in the schools, enlarge the sphere of the teacher's instruction and influence, elevate his employment and office, connecting pleasant associations with it in the minds of the scholars and in the families to which they belong. It will raise the tone of literary interest and ambition among pupils, and relieve the dull routine of mere elementary instruction, by the pleasures of entertaining and useful knowledge. It will be a kind of connecting link, to unite the school with society around, and will naturally form the nucleus of an extended popular library, which by susequent yearly additions will contain the materials for a general acquaintance with all subjects of interest and benefit to the community.

"4. It seems necessary, in order to carry out and complete the work of school education, to provide some such supply of the means of reading. The elementary branches taught in the classes, are rather the instruments by which knowledge is to be acquired, than the acquisition itself. They constitute the preliminary training of the mind, and when this is in some good degree accomplished, how important that the pupil should have opportunity to employ his powers, in exploring the field of knowledge. The school teaches the boy to read; and gives him some elementary knowledge of various kinds which enables him to understand books. When this is acquired, we must give him the books, or our work is incomplete.

"5. Such a library of simple, interesting and instructive works, would exert a vast influence in preserving the morals of the community. An entertaining book is one of the strongest keepers a child can have. Its chain is invisible, and it neither chafes nor annoys the wearer. But it is more effectual than almost any other restraint. How many hours would such libraries rescue from idleness; from wicked conversation; from open dissipation and vice? how many from noisy brawls and savage fights? And this, too, just in the most important crisis; for, if a young man's character is saved till ho is twenty-one, it is in general saved for life. This plan also, by providing a source of enjoyment and improvement for all the members of a family *at home,* will strengthen the domestic relations and tend to revive and restore the love of domestic pursuits and pleasures. The experience of ages shows that mankind can exist safely and in happiness, only in the form of a vast congeries of *families;* and the more we can strengthen the *love of home,* and bring means of improvement and happiness to every man's fireside, and keep the inmates of the household at home, the better for the virtue and solid happiness of the community.

"6. It will be a very effectual mode of supplying the population generally with the means of knowledge. Through the scholars, the books will find their way, in constant rotation, to all the families around; and many circumstances will conspire to cause them to be extensively read, by the adult population. Parents are always specially interested in their childrens' pursuits, and often like to read themselves what their children are reading. And the interesting nature of the subjects, the simplicity and directness of the style, and the practical utility which will every where be aimed at, will fit these works peculiarly to the wants of a large class of our population too much engrossed with cares, or wearied with the toils of life, or of too little mental cultivation to engage in more extended studies.

"7. The plan is a very economical one. The amount of useful result is very large, when compared wtih the expenditure. A book sold to an individual is commonly read but by few, and is then laid aside idle and useless. These books, on the contrary, will circulate continually, and be used by new readers in succession, till worn out. An edition of 1000 copies, in the ordinary way, will reach perhaps 5,000 or 10,000 minds. But on this plan, circulating among the families of a thousand districts, they will have opportunity to reach *several hundred thousand minds.* Indeed, if it were desired to make known a narrative of facts, as extensively as possible to the mass of a community, what cheaper or better mode could be devised, than to place a copy in every school to be loaned to the scholars in rotation? A sum not exceeding the ordinary endowment of a professorship in one of our colleges, will found such a national library; and enable the society to perpetuate its blessings indefinitely among the *rising generation* in our country. Tens of thousands, in our day, hundreds of thousands, millions, yet unborn,—would have their minds expanded, and their characters formed, under its benignant influence. Such a library placed in every school in our country, would seem to be one of the most effectual and desirable measures for the general diffusion of knowledge and the improvement of society, that could possibly be devised. Its benefits would be incalculable. It seems to the committee, that if the founders of such libraries as the Bodleian, the Harleian, and the Cottonian in England, had devoted one-half their munificent endowments in establishing a suitable library for the common people, with the means of giving it universal circulation among the towns and villages of our mother country, they would have accomplished incomparably more for the improvement and happiness of their countrymen and of the human race, than they have now done, by their princely gifts in the republic of letters.

"And they cannot but express the hope that the immense importance of such a benefaction may attract the attention of the opulent in our country, and that patriotic individuals may be found willing to give their influence and a portion of their property to the great work of diffusing among all classes of their countrymen, and through many future generations, the elements of a sound and wholesome literature."

"EXECUTION OF THE PLAN.

"All the arrangements for carrying the design into execution, are in a state of forwardness, so far as they can be, before the necessary funds are secured. It is estimated that $15,000 are required to manufacture the stereotype plates for 50 vols. If this sum were furnished, the library would be at once completely and permanently endowed, as arrangements can be made with publishers, if the plates are furnished, to supply the market fully and constantly, and defray all the expenses of manufacture and copyright out of the proceeds of the sales. Should, therefore, any benevolent individual, or the community, place in the hands of the society the means to procure these plates, the perpetual supply of the books, at the cost of $20 for the fifty volumes with their case, would be at once secured.

"The society take the liberty, therefore, to lay these suggestions before the community, and they solicit from any individuals who may be interested in the subject, a reply to this communication, offering either suggestions in respect to the general interests of the plan, or proposals for furnishing particular books, or aid in raising the necessary funds.

"By the constitution of the society, the annual payment of $5, or more, constitutes an individual a member; of $100, within any one year, a life member; of $500, a life director; and of $1000, within the same period, a life director, and an honorary member of the executive committee. Members of the society are also to be entitled to the privilege of purchasing publications at a reduced price; life members and life directors will be entitled to receive five per cent annually, on the amount of their payments in publications, if applied for within the year.

"Any individuals disposed, in either of the above ways, to aid the objects of the institution, are earnestly and respectfully solicited to do so, as soon as may be, through the treasurer, A. P. Halsey, Esq. cashier of the New-York Bank, to whom all communications relative to financial concerns, may be addressed.

"Any school or family, any lyceum or other institution disposed to subscribe for the library, or any individuals willing to undertake to supply the schools in a town or county, are requested to signify the same to the committee, and the number of copies desired.

"Editors of newspapers and other periodicals, friendly to the interests of education and the universal diffusion of knowledge, are respectfully requested to give this prospectus an insertion, and to co-operate with the committee in bringing this important object before the community, and securing its accomplishment.

"In behalf of the executive committee,
"LEONARD BACON,
"THOMAS COCK,
"TIMOTHY R. GREEN, } Sub Committee.
"GORHAM D. ABBOTT, Secretary.
"*New-York, Oct. 12th*, 1837."

Why is it best to bury Manure?

Animal matters decompose with facility when acted upon by moisture and air, the greater proportion of their elementary parts making their escape in various forms of combination, and leaving the earths, alkalies and carbonaceous matters remaining.

When this decomposition takes place beneath the surface of the ground, these gaseous compounds, as well as the carbon (which there is reason to believe assumes also the gaseous state by combining with oxygen,) may be supposed to be partially or wholly retained in the earth, to afford the matter of nutrition to the plants.

Purely animal substances, therefore, which thus readily decompose, do not absolutely require fermentation before they are mixed with the soil.

Vegetable fibre is, under certain circumstances, a slowly decomposing substance. When vegetables are green and full of juices [as all green crops and grass leys] they readily ferment; [hence the impropriety of wasting these fertilizing properties by cross-ploughing] but when the stems are dried, as in the case of straw and litter, they decompose with slowness, and the mixing them with animal matter hastens the putrefactive fermentation.

The principal animal matters which are mixed with the ligneous fibre of the litter, and which cause it to undergo decomposition, are the dung and the urine of the animals.—*Prof. Low.*

The practical lessons to be drawn from the above theory, are, 1. To make your cattle yards concave, or hollow in the middle, to retain the urine of animals, nearly the moiety of the manure. 2. To strew or feed your straw, stalks and other litter in the yard, to absorb the urine and other liquids there accumulating. 3. To apply this manure before it has undergone much fermentation, that the soil may inhale its gaseous portions. And we would add, 4. To apply it to a hoed crop, that the weeds and grasses, the seeds of which are blended with the dung, may be extirpated in the process of after culture.

Composts,

Are useful in two cases—1. To save fertilizing matters, which might otherwise be wasted or lost; as the urine of cattle, or the gaseous matters which are evolved from a dung heap undergoing fermentation. And secondly, to render soluble, and available as the food of plants, that which is not already so, as swamp earth, woody fibre, &c. But there is nothing *added* to the elements of fertility by mixing vegetable, animal and mineral matters in a compost heap. On the contrary, lime is known to be decidedly prejudicial when mixed with yard dung, and by some is thought to be so when mixed with peat earth, by forming with them new combinations that are insoluble.

Agricultural Exhibitions.

The agricultural journals which reach us abound in accounts of the cattle shows and agricultural fairs, which were generally held in October, from Maine to Kentucky. At the Kennebeck show, 3,000 persons are said to have been present, and 150 yoke of oxen, besides a corresponding number of other animals, were exhibited. Premiums were awarded upon a drill barrow and a root cutter, of recent invention, and upon apples, pears and other fruits. In Scott county, 26 silver cups were awarded;—in Lincoln 28, and in Woodford 35, all in Kentucky—as agricultural premiums.

The Weights of Grain,

Are materially influenced by climate, and are generally heavier in a northern latitude, or in an elevated district, than they are in a southern latitude, or in a low district. The cause of the difference we believe to be this—that in the former the heat is more moderate, and the grain is consequently longer in maturing, and acquires greater bulk and solidity. The like difference is also often found to exist, in some species, between that grown on cold heavy land, and on land which is light and warm. Disappointments often occur, in sowing heavy seed, from a northern or elevated district, in not realizing a corresponding weight in the product. These facts are in a measure corroborated by the following exhibit of the weight of grains for which premiums were awarded, on the 2d Oct. by the agricultural society of Bathurst district, Upper Canada, a memorandum of which has been sent us by H. C. Baker.

Fall wheat,	64 lbs.	2 oz.	per Westminster bushel.
Spring do	63 "	8 "	"
Common oats,	44 "	8 "	"
Potato oats,	46 "	6 "	"
Peas,	66 "	6 "	"
Barley,	54 "	14 "	"
Indian corn,	64 "	2 "	"

Highland Society.

The Highland Society of Scotland is about to institute a museum on a large scale. For several years the directors have been gathering together materials for a museum, and it appears the collection they have formed is now sufficiently extensive to justify the erection of a handsome building especially designed to contain it. It will contain models of all known agricultural implements, seeds, &c. with models of different varieties of stock of the most approved breeds. The society's first premium to have been awarded in Oct. was 500 guineas, for the application of steam to the cultivation of the soil; and gold and silver medals for reports of improved rural economy abroad, particularly in France, Germany and the Low Countries; and the society propose to take the earliest opportunity of communicating their details to the public.—*Herald.*

Profit of Agricultural Improvement.

In a late statistical account of Scotland, we have a striking illustration of the benefits of outlay in improvement, in the example of a Mr. Maxwell. In 1828, he commenced operations on a farm of 550 Scotch acres, on a great part of which it was difficult for the plough to enter sufficiently deep into the soil, because obstructed by stones imbedded, especially on the top of the subsoil. These lands were not then worth, in grass, more than 16s. an acre. At the date of the publication he had perfectly reclaimed 235 acres, by removing all the stones, to the depth of from 12 to 15 inches, and by making from 8,000 to 10,000 rods of drains. The whole expenditure amounted to nearly £5,000, or $22,200—less than $20 an acre. The five first crops taken from the reclaimed lands were worth $146 per acre, being an average annual product of about $30 upon each acre reclaimed, and far more than remunerating for the heavy outlay.

The Study of Agriculture,

Is recommended by a writer in the North American Review, in the following extract:

"Now, although the paramount importance of agricultural pursuits, over all others, is unquestioned, we suspect there is scarcely a school or college, in the country, where a single hour is devoted to the elucidation of their leading principles; and we doubt not, that many have finished their academical courses able, perhaps, to repeat whole volumes of metaphysics in the words of the author, while they have not merely acquired no knowledge, but have formed no conceptions of those familiar operations of the farmer and gardener, to which they are indebted for their daily food. Surely some few days of the ten years pupilage, through which so many of our youth pass, might be profitably given to subjects so interesting, as well as so important, as these."

Couch, or Quack Grass,

Is collected, washed and sold as cattle fodder in Italy. Children follow the plough, gather, wash, tie in small bundles, and market it, when not wanted on the farm. It is also found to possess medical properties, and is prescribed in decoctions, like sarsaparilla, for scorbutic patients. It is stated in the Farmers' Magazine, that upwards of 170,000 dollars worth of gramminia is annually sold by the peasants to the inhabitants of the city of Naples alone.

Prices of Wool in England.

We have often heard it remarked, and we have concurred in the opinion, that our woollen manufacturers can afford to make a greater difference than they do make, in the prices they give for prime Saxon, and grade wool. The expense of manufacturing the two kinds differs but little, while the price of the fabric made from prime Saxon is generally double that made from grade wool. In the London price current for August, we notice the prices of wool were as follows: Electoral Saxony from 4s. 2d. to 5s.; first German wools 3s. 2d. to 4s.; Spanish Merino from 1s. to 3s. 2d.; native sheep's do. 1s. 6d. to 2s. 6d. There the prices of wool seem to correspond with the prices of the cloths into which they are converted—the Saxon being nearly double to the Spanish—here they do not correspond with the price of the cloths which they produce.

Improved Cross of Sheep.

Charles Vaughan, a distinguished breeder and farmer in Maine, has published in the Maine Farmer, letters highly extolling his improved breed of sheep, which are a cross of the South-Down with the Dishly, or new Leicester. The particular points of excellence are large size, hardiness, early maturity, and, we venture to add, from the known character of the South-Downers—excellence of mutton. Lambs of fifteen days old have weighed 20 lbs. and at five months have reached 65 lbs. upon ordinary keep. There is nothing unreasonable in the supposition, that the breeds of domestic animals can be improved here as well as they can be in Britain, provided we bestow upon this subject the same judgment and care that they do there. From what we have seen of Mr. Vaughan's writings, and heard of his practice, we are disposed to believe that he possesses high qualifications as a breeder.

Agricultural Schools.

The Derry (Irish) Journal informs us, that three additional agricultural schools have recently been established in Ireland, by the National Board.

On Improvement in Horticulture.

Read before the Horticultural Association of the Valley of the Hudson, by J. Buel, *on the 28th Sept.* 1838.—*Published at the request of the Association.*

Recently notified that the gentleman selected to address you on this occasion, would fail in the performance of that duty, I have hastily prepared some remarks on the objects and promised utility of this association, which I beg leave to read.

Our first parent was placed in a garden, and commanded "to dress and to keep it;" thereby indicating, from the highest authority, that the garden is pre-eminently fitted for the performance of our highest duties, and the gratification of our purest pleasures. This construction of the Divine precept, is in accordance with the opinions of every enlightened age and nation. The garden has, by general consent, ever been considered a source of utility and of healthful employment—the best theatre for concentrating and displaying the beautiful and wonderful diversified varieties of foliage, flowers and fruits of the vegetable world—and a school for civilizing and socializing man, and of inspiring him with love to his Creator, and good will towards his fellow-man. Nor does the injunction seem to refer to the mere gratification of animal appetite;—for we read, that "out of the ground made the Lord God to grow, every tree that is pleasant to the sight, and good for food."

Gardening and Horticulture are in a measure synonymous terms. Gardening is divided into branches. It "is practised for private use and enjoyment," says Loudon, "in cottage, villa and mansion gardens;—for public recreation, in umbrageous and verdant promenades, parks and other scenes, in and near large towns;—for public instruction, in botanic and experimental gardens;—and for the purposes of commerce, in market, orchard, seed, physic, florists and nursery gardens." In all of these departments of Horticulture, we have great room for improvement, and great need of it; in all of them it is the object of this association to promote improvement, and in all of them they will effect improvement, if their efforts are seconded, as I trust they will be, by the intelligence, the taste, and the public spirit of the opulent gentlemen of our valley. It is the object of the association to introduce into this—our Eden—"every tree that is pleasant to the sight, and good for food"—to introduce, and to disseminate widely, all that is useful and ornamental in garden culture—all the fruits, flowers and culinary vegetables, that are worthy of culture, whether of foreign or domestic origin, which our soil will grow, and our climate mature.

It is not enough that many of the choice productions of the garden should be found with a few of the opulent. Those that are excellent should be known and disseminated widely. We should do good to others, if we would know the pleasures that spring from a generous philanthropy. By bringing these productions together at our semi-annual exhibitions, showing and comparing them, we can determine their relative merits, their proper names and synonymes,—can publish the result of these comparisons, and recommend and disseminate those which possess the greatest intrinsic merit. "All men will eat good fruit that can get it," says Sir William Temple; "so that the choice is only, whether one will eat good or ill;—and of all things produced in a garden, whether of salads or fruits, a poor man that has one of his own, will eat better than a rich man that has none." We seek to extend the luxury of good fruits to all, in order that the poor man who has a garden, may eat better fruit than the rich man who has none.

As I have remarked, gardening is co-existent with man. Its early history is too obscure to be traced. Suffice it to say, that in the best days of polished Rome, it was cultivated with taste and assiduity, and ranked with the fine arts; and that with these it sunk to obscurity in the downfall of that empire. All of the art that survived the shock of Vandalism in Europe, was preserved and cloistered with the monks during the dark ages. With learning it revived first in Italy and Holland; to which countries many exotics, and a taste for cultivating them, were introduced during the crusades. It was not until the reign of Henry 8th in the beginning of the 16th century, that gardening attracted much attention in England. Previous to this time, cabbages, and even pot-herbs, imported from Holland, constituted luxuries, found only on the tables of the opulent. During this reign, apricots, melons, herbs and esculent roots, were first introduced into the royal gardens. Among the new plants of that day is mentioned "the lilacke trees, which bear no fruite, but only a pleasant flowere." Improvement in Horticulture was greatly extended under Elizabeth and Charles the first. During the reign of the latter, the first work upon English gardening was published by Parkinson, under the title of "A garden of all sorts of pleasante floweres, with a kitchen garden, of all manner of herbs and roots, and an orchard of all sorts of fruit-bearing trees," which is yet quoted with high commendation.

About the middle of the 17th century, several valuable publications upon Horticulture appeared in England and France; and in 1734 Philip Miller published his celebrated Gardners' Dictionary, an original work of merit, which attracted general notice, and gave a new impulse to improvement. British and other foreign works upon gardening, have been greatly multiplied; and improvement has kept pace, with the increase of wealth and refinement, until horticulture has attained to a high state of perfection, as a science as well as an art, in most of the civilized countries of Europe. No gentleman of opulence or taste there, deems himself fitted to enjoy the comforts and luxuries of life, without his garden. Horticultural societies have been every where established,—princes have been competitors in them, for honorary rewards; useful and ornamental plants have been sedulously collected from every quarter of the globe, and innumerable new varieties have been added to the catalogue by the skill and industry of man. Within a few years, the splendid Encylopædia of Gardening, has been added to our horticultural works by the indefatigable Loudon, professing to give all that is interesting in the history, and all that is useful in the science, or in the practice of gardening. The society of London established a garden in 1818, and sent agents into every quarter of the world, to collect whatever could be found useful or ornamental. One of these agents, after traversing the United States and the Canadas, spent four years on the Pacific coast of our continent, exploring the country from California to the mouth of the Columbia, and thence across the continent to the Hudson Bay Factories, in collecting rare plants and seeds. In a subsequent voyage to the western border of our continent, this indefatigable agent was destroyed by a wild bull, upon one of the Pacific Islands. Yet the name of Douglass will be perpetuated in the cognomen of several new plants which he first brought into notice. Some idea may be formed of the extent of this society's labors and usefulness from the facts, that in its catalogue of 1830, are enumerated as growing in its garden, 3,400 varieties of hardy edible fruits, and 58 varieties of nuts, exclusive of 89 varieties of the fig, 182 of the grape, 56 of the pine apple, and 131 of the melon; nearly all of the four last named being cultivated in houses, with the aid of glass and artificial heat,—making an aggregate of about 4,000 varieties of fruits, which administer to the sustenance of man, independent of ornamental plants, which exercise a benign influence upon his mental enjoyments. The fruits in this garden have been classified, as it regards size and quality,—their form, colour, use and time of maturity noted, and their catalogue thus affords a guide in the selection of fruits for the climate to which they may be transferred for cultivation.

Enterprise in the acquisition of new fruits, and new plants, has not been confined to the London Horticultural Society. European governments, Horticultural societies, opulent amateur florists, and professional nurserymen, have sent their agents into remote parts of the world;—and the towering mountains of Asia, the Isles of the Eastern Archipelago, the burning sands of Africa, the inhospitable regions of Siberia, and the wilds of America, have been alike explored, for valuable and rare plants, to subserve our wants, and administer to our pleasures. The fruits of all their laborious researches lie within our reach, and a prominent object of this association is to transfer to the valley of the Hudson such of them as may found to administer to the wants and comforts of its population.

We are particularly indebted to the Flemings, for a great number of excellent new varieties of the pear. To the labors of Dr. Van Mons, of the University of Louvain, an amateur pomologist, we are indebted for about 400 new and excellent varieties of this esteemed fruit, some of which are in eating through the circle of the year. The late Mr. Knight, till his death president of the London Horticultural Society, also produced many new and excellent varieties of fruits, by artificial fecundation.—Samples of several of the new fruits thus produced by Mr. Knight and Dr. Van Mons are now exhibited upon your table.

From the comparatively restricted means of a new country, gardening has with us been limited to the useful, seldom aspiring to taste and elegance. But even in the useful branch we have ample room for improvement. We have no great central point for collecting and comparing, the indigenous fruits of our country, and for disseminating the excellent through our land. Of the apple, plum and peach, it is believed we have as fine native varieties as are grown in the world, and yet they are but partially known and but partially enjoyed. Individual exertions are too limited and feeble to effect the desired object. It can only be done by the combined exertions of many, influenced by a common impulse, and directed to a common end. In this age, no great good can be effected in any branch of public improvement, without the concentrated exertions of associate bodies. The garden culture of fruits and esculent vegetables, has hardly yet commenced in many districts of our valley, while in other districts the culture is but imperfectly understood—the relative merits of different varieties are not appreciated, and their value, in promoting the health, economy and comforts of a family, unknown or disregarded. Few of the fine varieties of fruit, or of the other choice products of the garden, are seen in passing through our country. Yet twenty years has done much to improve our Horticulture; and we have abundant reason to anticipate far greater improvements in the twenty years to come.

How few of our garden products, which are now considered, at least in imagination, indispensable to our wants, are the natural products of our country. Hardly one in twenty is indigenous in our soil. Our fathers have been collecting them, and we have been collecting them, through the lapse of centuries; and yet, how comparatively small is our stock, compared with what Providence has provided for the wants and comforts of man. We are strangers to many, very many, that grow naturally in our own country. And as to varieties, nature and art are every year multiplying them, under the same laws that multiply the breeds of our domestic animals, and that are diversifying the human countenance. Did our gardens contain only the plants that are indigenous to our country, the supply would indeed be scanty. But Horticulture has laid almost every clime, and every country, under contribution, to administer to our wants, and to gratify our senses. Most of our grains, and a large portion of our fruits, and esculent roots, derive their origin from other countries. The greatest part of them came to us from Great Britain and Holland, which received them from Italy, Italy from Greece, and Greece from Asia. Rye and wheat are indigenous in Siberia and Little Tartary; rice is the natural product of Ethiopia; buckwheat of Asia; kidney beans of the East Indies; the beet and onion, of Spain and Portugal. Peas came from the south of Europe, artichokes from Brazil, peppers and cucumbers from India; the egg plant from Africa; the tomato from South America; the pumpkin from Astracan; the ruta-baga from Sweden; the cauliflower from Cyprus; and the asparagus from Asia. Our fruits originated in countries equally remote from each other. Without pretending to decide upon the disputed questions, whether all the cultivated apples have originated from the wild crab, or whether any of our good varieties existed here when our shores were first visited by Europeans, I can say this much, that we have esteemed varieties of this fruit now under culture, which originated on the banks of the Po and of the Danube, of the Rhine and the Oder, of the Seine and the Thames, and on the shores of the Baltic and Caspian. The peach came from Persia; the plum from Syria; the cherry from Pontus; the quince from Austria; the almond from Barbary and China, and the pear from Europe. Our pot-herbs and cultivated medicinal plants, are also most of them exotics: parsley is from Sardinia, pursley from South America, nasturtium from Peru, thyme from Spain, sage from the south of Europe, savory from France, marjorum from Sicily, rhubarb from Asia, and balm from Switzerland. So also of our flowering shrubs and plants; the pink, the daffodil, and narcissus, are from Italy, the dahlia from Mexico, the ranunculus and anemonie, from Cappadocia; the hyderange, balsam and camelia from China and Japan; the tulip and hyacinth from the Levant; the tuberose from Ceylon, and our finest peonies from the "Celestial Empire." And of trees, we are indebted to the north of Asia for the ornamental horse-chesnut, and to the Indian islands, for the towering ailanthus. These are but a small portion of the contributions which Horticulture has gathered from foreign lands, for our convenience and pleasure; and every year adds to the list new genera, species and varieties. Providence seems to have apportioned its bounties among the different nations, as if to admonish them of their mutual dependence upon each other, and to excite in them a spirit of christian philanthropy and benevolence.

Private gardens of great extent and beauty abound in most of the countries of Europe, and they are maintained at a princely expense. In these not only hardy fruits and vegetables are forced to early maturity, by artificial means, but most of the tropical fruits are brought to perfection, by the aid of hot-houses and walls.—Strawberries, in this way, are produced for the table in April, melons in May, grapes and peaches in June, and pine apples at almost every season. It is assumed, that in Britain, a gentlemen may derive from his garden, with the aid of glass and artificial heat, a more varied and richer dessert, throughout the year, than is to be met with on the most luxurious tables in any other country. And yet the summers of England are so cool, that the peach, grape, melon &c. require the protection of a wall or glass, to bring them to maturity; and even our fine Spitzenbergh apple does not ripen well there without a wall. Gardens of this description, though generally on a limited scale, may be found in the vicinage of our commercial towns, and will doubtless be multiplied as we advance in wealth and horticultural improvement. These cases of high improvement, or rather extravagant refinement, in horticulture, are not mentioned as models for general imitation. They indicate an expenditure which few here can prudently indulge in if they would. Yet where there is the ability, and a disposition to extravagant expenditure, it may be indulged in, in horticulture, with advantage, rather than prejudice, to public morals and public usefulness. The examples to which we refer, furnish models of improvement, which we are at liberty to adopt on any scale that shall comport with our desires and our means.

Public nurseries, which belong to Horticulture, are highly useful to all communities in which they are located. They serve to introduce and concentrate the vegetable productions of every country, which are likely to subserve our wants or administer to our rational gratification. The interchanges which take place between those of Europe and America, are now managed with such facility, that a new fruit, or a new flowering plant, which attracts notice, and acquires value, on one continent, in a year or two becomes common in the nurseries of the other. The numerous horticultural periodicals of the two continents, make us early acquainted with whatever is new or valuable in either, and a single season serves to propagate and to disseminate the desirable plant on both. In this way we have been enabled to obtain the fine new varieties of Flemish and French pears, in many instances before they had fruited in England. The dahlia, in its natural single flower, was first introduced into France in 1801, and subsequently into England. The skill of the horticulturist has since transformed it into a double flower, and imparted to it all the colors and tints which are gratifying to the human eye. This ornament of the garden, which is now found at all our nurseries, is termed by common consent, "The King," as the rose has been called "The Queen of Flowers." And as regards fruits—I was instrumental in bringing into notice, seven or eight years ago, a fine new apple, the *Jonathan*, grafts of which I forwarded to Europe. Five years ago I noticed it in the catalogue of the Lon. Hort. Society, with the names of many other of our local fruits which I sent, and also in catalogues from the Island of Jersey, and from Hamburgh. The stroat apple which I sent at the same time had produced fruit in 1830, in the Lon. Hort. garden, and was classed, as it deserved to be, among the first quality of apples. The ailanthus was first brought to our country eight or ten years ago, by one of our consuls, from farther India, and it is now growing, I believe, in almost every state of the Union.

As having particular relation to those who depend upon market gardens for horticultural productions, for daily use, I take occasion to remark, that the quality of market garden productions depends materially on the judgment and liberality of the buyer. The object of the gardener is profit; and so long as the purchaser regards the price rather than the quality, he will continue to raise those varieties which give him the greatest products, which are generally those of inferior quality. The difference in the varieties of the same vegetable are manifestly great. This exists not only in their flavor, but in their nutritious and healthful properties: some varieties, particularly fruits, being absolutely prejudicial, while other varieties of the same species, are highly conducive to health. In the potato, for instance, the difference in nutritive matter amounts to nearly a half in different varieties. Some of the coarser kinds yield but 14 and 16 per cent of nutritive matter; while some of the finer kinds have given 28 per cent. And it is worth regarding, that good quality is almost inseparably connected with grateful flavor.

Horticulture, as an employment, is highly conducive to the healthful vigor of the body, and to an agreeable exercise of the mind. The labor it demands, is neither severe in degree, nor monotonously tiresome in kind.—It affords continued change and variety. The interesting objects of which it has cognizance,—as the germination of the seed, the development of the leaf, the growth of the stock and branches, the expansion of the flower, the swelling, maturing and gathering of the fruit, and the diversity in foliage, flowers and fruit, of the various vegetable families under its care, present to the mind, capable of appreciating and admiring the beauties of the vegetable kingdom, a succession of the most agreeable sensations.

As a recreation, Horticulture offers all the pleasures I have enumerated, without the fatigues which accompany its manual operations. What more grateful, to the sedentary and the studious, or to him who is habitually involved in the mercenary cares of business, than the relaxation afforded by a well kept garden, which exhibits to the senses, the fragrance, the beauty, the order and harmony, which Providence has imparted to the vegetable kingdom. Here is nothing to awaken jealousy, to excite distrust, to beget envy—or to inflame any of the grosser passions; but every object is calculated to tranquillize the mind, to soften down the asperities of his nature, and to beget, towards his fellow beings, feelings of kindness, philanthropy and love.

As a science, Horticulture is rich in stores of intellectual wealth and usefulness. It embraces glossology, which teaches the names of parts of plants; phitography, or the nomenclature and description of plants; taxonomy, or their classification; vegetable organology, or the external structure of plants; vegetable anatomy, or their internal structure; vegetable chemistry, or primary principles of plants; vegetable pathology, or the diseases and casualties of vegetable life; vegetable geography and history, or the distribution of vegetables, relatively to earth and to man; and the origin of culture, derived from the study of vegetables.

It also embraces the study of the natural agents of vegetable growth and culture,—as earths, soils and manures; the agency of light, electricity, heat and water, in vegetable culture, and of the atmosphere in vegetable development.

Whether we regard Horticulture as an art, or a science; whether we consider it as administering to our wants, convenience and pleasures, or as promotive of health and useful knowledge,—it has high claims to our notice and regard.

I present upon your table, for examination, gentlemen, more than one hundred named varieties of the apple and pear, collected from my grounds, which twenty years ago were a barren waste; and I might have added many others of doubtful or inferior character. Those presented have all been recommended as superior fruits, at the season of maturity, either for the dessert, the kitchen, for preserves, or for cider. They are the natural products of the northern and middle states, of Canada—and of Russia, Germany, France, the Netherlands, and Great Britain. They include of course only late autumn and winter varieties. Yet these fruits form but a small portion of the kinds which are to be found in our valley—much less in our country. Though we have a great many *good* kinds, there must be but comparative few that can be denominated *excellent*, or *best*. The only way to determine which are the best, is to bring the different varieties together, and to judge of them comparatively, at the season of their maturity. How desirable it is, that when starting in our pomological career—when selecting the fruits that are to administer to our enjoyment and our profit, through life, we be able to select the best kinds? But who is now a competent judge in these matters? What individual knows the comparative merits of half, or a quarter, of the fruits which abound in our land? Not one among us, I venture to say. How shall we then acquire the requisite knowledge? We have at present no competent guide to direct us in the selection. Individual effort is incompetent to the labor of classifying and describing all our best fruits. It can only be effected here, as it has been done in England, by the joint efforts of an association—by bringing together the various kinds, testing their qualities, and establishing a standard of their relative merit, for the various uses for which they are adapted. This subject is so deeply connected with the comfort of all classes of our citizens—of the buyer as well as the cultivator of fruit—that I venture to recommend it to the early attention of the association.

The introduction of new and valuable varieties of fruits, seeds and ornamental plants, from different sections of our own country, as well as from the old world, should also engage our early attention. Many facilities present for effecting this. First, by a correspondence, and interchange of plants, seeds and fruits, with horticultural associations at home and abroad. Secondly, through the depot established at Washington, under the direction of an enthusiastic friend of rural improvement, H. L. Ellsworth, Esq. the commissioner of the Patent Office. Thirdly, through our naval, commercial and travelling citizens. Our Corresponding Secretary, who has tendered his resignation in consequence of being about to take up his residence for some years in France, has kindly tendered his services in this behalf—and his services there, in forwarding the objects of the association, may be rendered extensively useful. After all, much, very much, will depend upon our individual exertions. If we show a spirit to go ahead, and to be useful to the community, assistance will be tendered from every quarter. But only those who *do* exert themselves, can or ought to expect assistance from others. We must put our own shoulders to the wheel, before we call upon Hercules. We *can* render this association pleasant and useful to ourselves, and highly beneficial to the public, if we but resolve to do so. But unless we set out, and persevere, in the resolution to do so, we had better suffer the association to die in embryo, and to forget that we had the ambition to be useful in promoting horticultural improvement, but lacked the resolution and the spirit to carry out our laudable design.

In conclusion—to the gentlemen who have interested themselves in getting up this exhibition, and particularly those of a sister state, whose contributions of superior fruits and flowers afford the strongest incentive to perseverance on our part, I feel myself authorized to tender the grateful acknowledgments of the association. A multiplicity of circumstances, and I may say of misapprehensions, combined with protracted bad weather, have tended very much to diminish the interest of our first exhibition; and yet I believe I may venture to say, that there has never, on any occasion, been collected in our state, a greater number of excellent varieties of fruit, or finer samples, than has been exhibited on this occasion; and although the season has been highly unpropitious to the floral department, yet the exhibition of fine dahlias, the favorite flower of the season, has been peculiarly brilliant. We have no reason to despond, but much to induce perseverance and renewed exertion. We have laid the foundation of improvement in that branch of industry which administers largely to the wants and elegancies of life. We can rear the superstructure. We can *deserve* success, though we cannot *command* it. And even the high satisfaction of doing this, is a consoling, if not satisfying reflection, to him who derives pleasure in laboring for the public good.

Advantages of Planting Fruit Trees on Declivities.

Dodart first observed that trees pushed their branches in a direction parallel with the surface of the earth. If a tree stands on a steep it pushes both towards the hill, and towards the declivity; but on both sides it still preserves its branches parallel with the surface. As there is an attraction between the upper surface of leaves and light, I am also persuaded, though not equally certain of it from experiment, that there is an attraction of the same nature between the under surface of leaves and the surface of the earth. This I consider the true cause of the phenomenon;—I had long observed that the most fruitful orchards, and most fertile trees, are those planted on a declivity, and the steeper it is, though not quite a precipice, the more fertile they prove. It is well known that the spreading of trees always render them fruitful. On a plain they incline to shoot upwards; and therefore art is employed by skilful gardeners, and applied in various ways to check their perpendicular, and to promote their lateral growth. But this point is obtained on a declivity by nature. There a tree loses its tendency to shoot upwards, and in order to preserve its branches parallel with the surface, is constrained to put them in a lateral direction. Hence an important rule in the choice of orchards and fruit-gardens.—*Rev. D. J. Walker.*

There is another advantage in planting on declivities, particularly where there is a retentive subsoil—water does not stagnate about the roots of the trees, as is often the case upon level surfaces, but passes off freely down the inclined plain, and the trees are consequently more healthy and vigorous.

Notices to Correspondents.

We received, too late to be noticed in our last, a communication from a *mercantile* correspondent, expressing a strong inclination to become a farmer, but who is deterred by the fear, that, like many others who start in a rural career, he will become tired of farming and the country, and sigh again for city life. He askes us to explain the causes of this frequent disappointments and to suggest the antidote. We take the cause of the disappointment generally to be, that when city gentlemen turn farmers, they place their dependance of enjoyment upon wrong objects—upon the fruits, and not upon the labors of the farm. Accustomed to the busy throng,—possessing little knowledge of their new business, and either not the disposition or the patience to acquire it, their time hangs heavily on their hands; they soon find themselves disappointed in their expectation of profit and of pleasure, without a manly effort to secure either, and ennui drives them back to the city. The antidote lies in taking a direct and active interest in the labors and business of the farm—of devoting to it his mental, and at least a portion of his physical powers—and of persevering in his efforts till he understands something of the theory, and is familiar with, and can direct with judgment, the practical operations of the farm. Having attained this point, and conformed his habits of living to his situation, there is little danger that he will again sigh for city life.

We received also, cotemporaneously with the preceding, a communication from a *medical* correspondent, who is now a noviciate in husbandry, and who has described his farm, and asks our instructions in its management. We fear our medical friend underrates the business of farming, and over rates our capacity for instruction.—Should we ask his direction for the medical treatment of our family, although we should attempt to describe to him their constitutions and habits, he would probably reply to us, that medicine is a profound science, acquired by long study—an art, thoroughly mastered only by long practice—that he could only give general direction for the treatment of diseases—and that all special directions must be preceded *by an examination of the patient to be prescribed for*. Our correspondent will see from this analogy the task he has imposed upon his, and that we might subject ourselves to the charge of *quackery*, were we to attempt to prescribe in his particular case. A knowledge of agriculture cannot be infused into one by *inoculation*. It must be acquired *the natural way*. As a science it must be acquired by patiently studying the principles upon which it is based. As an art, it demands persevering practice to become a competent master. All we can do, is to advise Dr. H. to study agriculture as he studied medicine—make himself familiar with the nature and qualities of his soil, tamper a little with experiments, notice their effects, and he will ultimately settle down upon the best modes of practice. It may seem hard for him to undergo a second course of studies; but he may rely upon it, that the best counsellors are personal knowledge and experience. The Doctor, we believe, will find most, or all, of his special questions answered in the volumes of the Cultivator, either directly or indirectly.

Draining.—B. F. Wells, of Suffolk, has sent us a description and diagram of a salt and fresh meadow, which is rendered in a measure valueless by reason of the fresh water which saturates it, and is subject also to be inundated with sea water at high tides. He askes our advice as to the best mode of reclaiming it. The salt water must be kept out by an embankment, and gates that close with the flood tide, like those we have seen at Newark, N. J. The source or fountain of fresh water must be ascertained. If it is in the surrounding high grounds, it may be intercepted and carried off by underdrains, sunk into the hard pan, above the level of the meadow. It may be extended, if necessary, entirely around it. If the source is in the bottom of the marsh, the evil seems incurable, as it would seem to lie too low to be drained, without permitting an influx of salt water, at high tide, through the underdrains.

Influence of agriculture and manual labor schools.—We have two communications on this subject, which, we are sorry to say, are too carelessly written to appear without correction, which we have not yet found time to give them. Both of our correspondents seem to consider manual labor as agricultural schools, and that they are calculated to promote general improvement in the science and practice of agriculture. This, we believe, is not pretended to be the case in any existing manual labor school; and if so, we have not been advised that it has, in any instance, been successful. The pupils in these schools are not generally designed to be farmers. They work for health and economy, and not to learn the trade and mystery of farming. We should be sorry to have it believed, that these are a fair test of the utility of agricultural schools.

Miller's Tolls—We are not aware that any benefit will result, either to individuals or the public, from prolonging this controversy. It seems to be admitted on all hands, that the miller has a right, by custom if not by law, to take a *tenth* for toll—and no more. If our Oswego correspondent has had a *twentieth* abstracted from his grists, as he alleges, he has been cheated, as we have been; and he has his remedy against the miller—or he may send his work to a more honest man.

CORRESPONDENCE.

On Rotation of Crops.

Dear Sir—Although I have not the pleasure to know you personally, such is my confidence in your devotion to the cause which you are so successfully laboring to promote, as well as in your liberal indulgence of opinions opposed to your own, that I shall offer no apology for the following remarks elicited by your interesting article entitled "Rules and Suggestions in Husbandry." All of those I deem highly valuable: but there are a few which, although they have almost become axioms, appear to me at least *doubtful*, notwithstanding they are sustained by such a host of celebrated authorities, that any individual who ventures to question them incurs the risk of being called quite presumptuous. This risk, however, I am willing to run in, the hope of exciting some abler and more experienced agriculturist than myself to a full discussion of a subject so important to all cultivators of the soil as that which forms one of the chief topics of your article,—I mean, *the rotation of crops*. But to proceed with my comments.

In your 18th rule or suggestion you say,—"The natural fertility of a farm cannot be kept up or increased, where arable and mixed husbandry prevail, from the resources of the farm stock, without resort to an alternation, or change of crops. Although the diminution of fertility may be imperceptible in some extraordinary cases—and although some soils seem naturally and peculiarly adapted to certain crops,—yet, where the same crop is grown on one piece of ground in successive years, deterioration as certainly goes on as the sun shines by day."

Here, in the first part of your second sentence, although you evidently make an exception to the universality of your rule, *that* exception is entirely done away by the positive unqualified assertion in the last part. This naturally suggests the following question;—how is an imperceptible deterioration to be ascertained, and if *that* be practicable, can it be worth regarding in any of those cases, where it is so slight,—so gradual that nobody can see it?

The 19th rule declares, "that two white, or grain, or culmiferous crops, should not be made to succeed each other in the same field."

Now, in opposition to the universality of these rules, the facts which have fallen under my own observation, together with those communicated to me by perfectly veracious agriculturists, are so numerous and remarkable as to have made me, if not a decided infidel, at least a sceptic in regard to the absolute necessity of a rotation in crops, for the purpose, either of creating or preserving the fertility of soils. That *some* rotation is generally beneficial, and in a degree well worth regarding, I have no doubt. But like thousands of other good things, I feel equally confident, that its benefits have been immeasurably exaggerated, and thereby have prevented its adoption to the extent to which it might and probably would have been carried, had no Baron Munchausen-tales been told about it. Many an excellent practice has failed to become general, solely from the circumstance that the first who adopted it on the recommendation of those who claimed to be the inventors, did not half realize the promises made in its behalf. Exaggeration is the besetting sin of almost all inventors and discoverers, and this folly often deprives them both of the credit and the profit of their discoveries and inventions.

Permit me now to state a few of the facts which have produced my scepticism. The two eastern shore counties of Virginia comprise a large extent of country. The soil is generally sandy, and not such as is usually deemed either the most fertile or the most lasting: yet all with whom I have ever conversed, confidently declare, that their lands at least "hold their own" although they have been generally cultivated, for a long series of years, without rest, in alternate crops of corn and oats, and without apparent diminution of the amount of produce. The inhabitants ascribe this to a natural growth which they call a bean, but which is in fact a pea that almost invariably succeeds the oat crop, and is turned into the land when ploughed up for corn. Here, then, is a formidable exception of great extent, to the rotation creed, as well as to the poisoning system of Monsieur Candolle and others: for in two very large counties of Virginia, two white crops of grain constantly follow each other every year, without any perceptible deterioration, as the owners and cultivators of the soil all assert; and this too, in most cases, without any return to the land, of fertilizing matter, except the dead natural growth of the pea. Could this possibly happen, either if rotation was as indispensable as it is alleged to be; or, if the poison-fanciers were right in their strange notion? If *their* creed were true, neither corn nor oats could any longer propagate their breed in Accomack or Northampton; for both would have deposited by this time so much deadly poison for their offspring, that none could ever germinate, much less continue a healthful existence. Again, if your opinion be correct, the average equality of the corn and oat crops in these counties, for so long a period, without any alternation whatever, except from one to the other, can be accounted for only by supposing either that the soil of our eastern shore counties originally contained such a superabundant store of the peculiar food of corn and oats, that half a century has not sufficed to exhaust it; or that the natural growth of the pea restores annually, the quantum sufficit of this food to maintain from year to year the alleged equality of product. The fact itself cannot be doubted, unless we can persuade ourselves to believe that every cultivator in the two counties has deceived himself, which is hardly possible.

In several other parts of Virginia, I myself have seen pieces of land whose owners have assured me had been constantly cultivated in corn without rest, for ten, fifteen, and twenty years, and in some cases still longer, without apparent diminution of crops except in bad seasons. The same assurance has been given me by many tobacco-planters in the James-River country, as to the continued culture of that crop, on the same land,—even for thirty years in succession; and likewise of corn and wheat alternately, for similar periods, on other portions of that territory. Only a few days ago, talking on this subject with a friend from one of our counties bordering on the Chesapeake, he told me that the best crop of wheat he ever made, was on a piece of land from which he had taken a crop of oats only a few weeks before he sowed the wheat; and I have heard similar statements from others whose word I could not doubt. In most of these cases I understood that no manure was used, unless the weeds and stubble could be so called, which were turned under by the plough.

Take one fact as to cotton. Several years ago I was accustomed to visit a near relation who, for twenty odd years, cultivated this plant in a few acres near his house,—the soil of which, although good, appeared to have nothing peculiar in it,—nothing indicating any essential difference between that and other common soils of similar quality, on our tide-water-rivers. I saw the crop of cotton almost every year during the greater part of the time, and never could perceive any difference, in similar seasons. The proprietor himself always assured me he found none in the product, but what was manifestly attributable to the variation of the seasons,—the crop of one good year being quite equal to that of another. The only manure given to this cotton was drawn wood ashes, in which the seed was constantly well rolled before planting.

Let me now state a few facts as to garden vegetables, in opposition to the rotation doctrine, and the supposed necessity for a change of seed. In the tide-water portion of our state, I once saw, at a lady's table, some Irish potatoes of so good a quality, that I was induced to inquire where she procured her seed, and how she cultivated them. She informed me, that she had used the same seed for eighteen years, and had raised them every year, in the same square in her garden, only adding the usual quantity of manure in the trenches, every time of planting. The soil of her garden appeared to me much the same as is common with us. Of some other table-vegetables I can speak from my own experience; for example, the English pea, (as we call them,) the snap-bean, and the Siberian cale.* These I have cultivated for a number of successive years, without any change of seed or situation, and in similar seasons have never discovered any difference, either in quality or quantity. The manure used has been either from the horse stables, or drawn wood ashes.

To the foregoing statements it may perhaps be objected, that they contain more matters of opinion than of fact. True it is, that I have given no results of actual comparative measurements; but it is hardly conceivable that so many farmers and planters as have referred to, could have been cultivating corn, wheat, oats, and tobacco, for nearly half a century, without over measuring their crops. This is never omitted, although in some instances probably, less accuracy may be practised than in others. Still a measurement is always made with sufficient particularity to warrant the opinions I have stated, derived from so many different individuals, in different parts of Virginia, and concurring with a degree of unanimity which could hardly be possible unless sustained by similar facts. Taken all together, they appear to my mind most indisputably to refute the plant-poisoning-doctrine; and if not greatly to invalidate the rotation-creed, at least to throw in its way, some obstacles which I can perceive no satisfactory means of removing. If there are any I should be highly gratified to learn what they are. I am not conscious of any prejudices on either side; but notwithstanding the fearful odds against me, I must believe from an experience of nearly "three score years and ten," that some very profitable farming *may be* rationally expected without any rotation of crops, provided only that suitable manures, and in sufficient quantities, be annually applied to the arable parts of every farm.

Let me beg you, my good sir, not to mark me down as an utter infidel—guard the rotation system. To a considerable extent I profess myself a believer; but acknowledge, with all due humility and apprehension of reproof, that I am a bit of a sceptic, as to some of the marvellous benefits ascribed to the mere alternation of crops; for in almost every case to which I have paid particular attention, the effects seemed quite as much attributable to manure, as to rotation. Still I am willing to admit—nay, I finally believe, that the best system of husbandry is inseparably connected with, and dependant upon both.

In connection with this subject, there is an opinion very prevalent among us as to the comparative power of different crops to exhaust or improve land, which seems to have more in it of fancy, than of fact. I am aware that some European gentleman, (of what profession I do not recollect,) has published a table, which has appeared in our agricultural papers, wherein he professes to have ascertained this power, to the ninth part of a hair; but has left us utterly benighted, in the slough of despond, as to the modus operandi,—although, if he is a real practical agriculturist, he might readily have concluded his table would prove such a stumbling-block, such a pons asinorum, in the way of us American clodhoppers, that we never should be able to get over it without farther aid, than the mere tabular statement affords. The existence of the exhausting power in all crops, is too manifest,—too much a matter of daily observation to be denied; but what crop exerts it most, and the exact degree of such exhaustion, I humbly conceive, to be among the "unknowable things" of this world. One common notion, however, this table unquestionably *disproves*, which is, that some crops actually *improve land*, and hence are called *improving,—ameliorating crops.* Now, I would most respectfully suggest to all my agricultural brethren who read your highly useful paper,—(and I venture to call them brothers, because I myself feel the sentiment of fraternity for all,) that if any general rule whatever can be established on this subject, it may be expressed in something like the following terms: *All crops, if taken entirely off the land, exhaust in proportion to the number and size of the spongioles of their roots, and the time consumed in their growth and maturity; and none actually improve, but such, (if any such there be,) as return to the soil more of the food of plants, than they consume.* This I consider a universal rule; but if any one can produce what he believes to be an exception, I pledge myself at least to *the attempt* of disproving it.

A word or two in conclusion, and I shall cease to tax your patience with any more of my lucubrations. I assure you, in perfect sincerity, that they have been prompted solely, by an anxious wish to promote *our* cause,—*that* cause which I verily believe to be the main-spring, the only true source, both of individual and national wealth, prosperity, and happiness. If you believe this communication may, in any degree, contribute towards these vital objects, *then* I wish you to publish it; otherwise, it is my wish that you burn, or use it as waste paper. Its style and general character may possibly need some explanation,—nay some apology, with the graver, more solemn portion of our brethren. If such apology be required, here it is. *My* experience has thoroughly convinced me, that plain naked statements of facts in husbandry, however important they may be, are such soup meagre diet to most of our brethren, that very few, comparatively speaking, can be prevailed upon, ever to taste, much less to swallow such cookery. With this fact indelibly impressed upon my mind, I have endeavored to season the dish which I have offered to you and your readers, although it is with much fear and trembling, lest it may force upon your memories the old adage, —that, "God sends meat, but the devil sends cooks." I remain, dear sir,

Yours very respectfully,
JAMES M. GARNETT.

REMARKS.

We most cheerfully give insertion to the preceding communication, and not the less readily because some of its opinions seem to conflict with our own. We say *seem* to conflict—for we are still of the opinion, that were our views mutually understood, there would be found to be no great matter of difference between us. Besides, it is by free and liberal discussion—by the collision of opinions—that important truths are often elicited, and improvements made. The high standing of our correspondent, and his long practical experience in husbandry, will always render his favors acceptable to the conductor, and interesting to the readers of the Cultivator, however highly "spiced."

We must in the outset wholly disclaim being a disciple of the "plant-poisoning" theory of De Candolle and others. We have uniformly considered it illusory. But we do contend, that each species or family of plants require, and do tend to exhaust the soil, of specific portions of its fertilizing matters; and the exceptions taken by our correspondent do not seem to invalidate our general proposition. Our position is in a manner proved by the fact, that wheat requires carbonate of lime, clover, gypsum, &c. and that some soils will bear a succession of some kinds of crops, and not of other kinds. A soil may contain a large proportion, say twenty per cent, of the specific of food wheat, or corn, or tobacco; and as not more than a half, or a quarter per cent of this may be required or taken up, by a single crop, the supply would last forty or fifty years, without *perceptible* diminution, and yet at the end of the period would become wholly exhausted of it. For we believe the elementary food of plants combines in definite proportions, and that crop takes from the soil, of its specific food, not in proportion to what the soil contains of this food, but only what is required, by the laws of vegetable nutrition, to supply its absolute wants. We are induced to this conclusion by the fact, that on analysis, every farm crop is found to contain about the same elementary matters, and in the same proportions, on whatever soil they are grown—poor or rich—which they would not do were they permitted to gorge themselves with their favorite food, or were wholly deprived of it. It was these considerations which induced us to say,—"that when the same crop is grown on one piece of ground, for successive years, deterioration as certainly goes on as the sun shines by day."

And how is this proposition disproved, or even weakened, by the facts detailed by our correspondent? He tells us, in the first place, that corn and oats have been alternated in Accomac and Northampton, for half a century, without perceptible diminution of product. Are corn and oats "the same crop?" Besides, the pea, the bean, or the vetch, which always accompanies the oat, and which is turned under as food for the corn—is this nothing?—is not this virtually a *three* course system, instead of being a succession of the "same crop?"

The great wheat grown after the oat crop may be explained, though we do not mean to say correctly, by supposing what often takes place, that the oats were sown on a fresh turned ley, and that the vegetable matter of the soil only became soluble, or but partially so, after the wheat was sown.

The potatoes and the garden products, it seems, received an annual supply of manure—and this manure probably abounded in the specific food of the plants. Every field of a farm would probably continue to yield like the potato, the pea, &c. and supersede rotation of crops, "provided only," to use our correspondents words, "that *suitable* manures, and in *sufficient quantities*, be annually applied to the arable parts of every farm." It is the difficulty of obtaining this manure, of suitable quality, and in sufficient quantity, from the available means of the farm, thus annually, for every arable field, that a resort to alternating crops is deemed necessary.

The truth of the matter seems to be, that we meant to give *general* rules, and our correspondent has shown, that like all other general rules, they are liable to *particular* exceptions But let us put the question fairly: How will the general principle, or rather the want of a due observance of it, apply to Virginia, for instance? Have not successive crops of wheat, of corn, or of tobacco, greatly deteriorated some of her once fertile soils? Have they not reduced thousands, and tens of thousands, of her good acres to comparative sterility—to unproductive commons? If these questions are answered in the affirmative, they will in some measure sustain us in our general rule. If in the negative, we would ask, from what cause then has deterioration resulted?

We have said thus much in defence of the theory of rotation, not in the spirit of controversy, but because we deem it a valuable collateral branch of improvement whenever it can be reasonably adopted. So far as the experience of twenty years has enabled us to judge, we think its advantages manifestly great, not as a substitute for manure, but as an auxiliary. —*Cond. Cult.*

Rotation of Crops.

Bucks Co. Pa. 9th mo. 27th, 1838.

J. Buel—I observed with pleasure, in the 7th No. of the Cultivator, the following course of crops suggested. 1. Roots or Indian corn, with long manure upon the sod: 2. Grain, with grass seeds: 3. Grass, for two years.

Wheat, rye, barley and oats are the principal grains with which I am acquainted. But as clover, and I expect grass seed generally, takes but poorly upon oats, I think it would be prudent to discard that grain altogether in such a rotation. The others may any of them succeed corn; but wheat or rye cannot, either of them, well be sown after beets or turnips; and I suppose, as a general rule, not after potatoes, parsnips or carrots. Barley, then, appears to be the only alternative after roots.* But as it will not be advisable, as a common practice, to give up "bread stuff," we must raise wheat or rye, and therefore corn. If, then, we confine our rotation to corn, wheat or rye, and the grasses, we drop "an important link in the chain of alternation," and thereby lose "one of the best gifts which modern improvement has bestowed upon husbandry," ROOT CULTURE: and also introduce the unadvised plan of putting one crop in the ground soon after another of the same kind has been taken off. To obviate these difficulties the following rotation suggests itself: 1, corn: 2, wheat, or rye: 3, grass: 4, roots: 5, barley: 6, grass. There are two particulars in this course upon which I wish to be better informed. Wheat and barley, I think, exhaust nearly the same kind of nourishment from the soil, or require the same specific food. If this is a fact, could there not be some other crop profitably substituted for barley, which would not feed so extravagantly upon the elements which produce the "staff of human life?"

---

* This I beg leave to recommend as preferable to all other winter-greens.

In some parts of Jersey rye is sometimes sown among corn, early in the fall, and a good crop mostly reaped the following summer. But to put wheat in after corn it is necessary to cut up the corn and carry it off previous to ploughing the ground. The stumps are then to be disposed of. And withal, some seasons, the corn does not ripen timely to afford an opportunity of getting the wheat put in properly, in season. The question then arises whether this is not the place to profit by some of the "powerful auxiliaries to the fold yard," mentioned in the following extract from the Cultivator.

"Green crops, that is, clover, buckwheat, rye, oats, &c. ploughed under as food for plants, are enriching crops, and powerful auxiliaries to the fold yard, but they are too seldom resorted to for this purpose."

Buckwheat and oats would require to be sown so late in the season that the ground would necessarily be exposed a long time to the scorching influence of the sun. I therefore conclude it would not be advisable to depend upon either of them alone. The advantage resulting from ploughing under a good clover sod for wheat is too well understood to need much comment. But sown among corn immediately after the last dressing it is rather too uncertain a dependence of itself for this purpose; though I have seen it sown at this time when it mowed a tolerable swath the following summer. I have known rye sown among corn for sheep pasture during the winter and early spring, and then ploughed under. And I have heard it said that rye, when pastured, becomes, like some of the grasses, almost perennial. The question appears to be, whether it would not answer a good purpose to sow rye and clover together, among corn, immediately after the last dressing, and pasture them during that fall and the following summer, and then plough them under for wheat? Is it not likely that such a practice would be an advantage to the wheat crop, and ultimately to the farmer's purse? If there would be any advantage in deferring the wheat crop a season after the corn is taken off, I would suggest the following course, desirous that any improvement may be pointed out which may present: 1, corn, with long manure upon the sod; sowed with clover and rye during the summer: 2, pastured and sown with wheat: 3, wheat, with grass seed; orchard grass where clover does not take well upon wheat after clover: 4, grass two years: 5, roots manured: 6, valuable substitute for barley, with grass seed: 7, grass one or two years. Poh! says the farmer, that course will never answer for me; I shall have to cut my fields all up into little bits. But, say I, the way to raise a good crop is to put in but little ground—do that well, and give it good attention afterwards. And we are thereby enabled to let such a length of time intervene between two crops, of the same kind, as to afford an opportunity for the elements which form the specific food for that crop to accumulate in such abundance in the soil as to induce a reasonable hope of an ample reward for our patience and pains.

I have no doubt but that in a course similar to this, the quantity of animal food for winter, would be greatly increased—thereby a much heavier stock might be kept: and accordingly, a large increase in the quantity of manure, which is said to be "the farmer's wealth."

But the desideratum appears to be a *valuable substitute for barley*, which will not impoverish the soil for wheat, and which is not quite so much of an enemy to young clover as oats. If it is a summer crop, to be fed in the fold yard, all the better for their land. M***

---

*At the north, where the grain-worm prevails, spring wheat is generally sown instead of the winter varieties. This may follow any root crop.

Benefit of Applying Plaster.

MR. J. BUEL—The beneficial effects of plaster on different varieties and species of vegetation are generally understood in expediting the germinating process, and in advancing the young and tender plant in its incipient growth; but a development of its power and virtue, at different periods throughout the growing process, under a certain state and condition of the earth and atmosphere, has not been either sufficiently investigated or made public. During the excessive heat and drought which visited this section of county, in common with many others surrounding, and in some instances detached portions as it respects the latter, our late summer crops, under ordinary circumstances, suffered severely; the potato crop being quite light, and the corn crop short of an average yield. About four acres of corn, planted on the 10th of May, on a gravelly soil in good condition, much of which, however, had not a depth of more than ten or twelve inches, reposing on a slate rock. On the third week of the drought the leaves began to fold, and continued so until all hopes of a crop were at an end: most of it was in silk and setting. I sowed half of the piece most injured with plaster, broadcast, over the leaves, a bushel and a peck the acre, after sunset. The beneficial effect derived from it was almost instantaneous; its attractive power in absorbing the moisture, and probably other fertilizing principles from the atmosphere, in three or four days restored its healthy appearance much; the other half of the field, more favored with a deep, rich soil, was apparently much less injured by the drought; the whole piece was plastered before it was hoed; the half receiving the second plastering turned out the greatest yield: the drought continued for ten days after the second plastering; a few rows on the margin, of a similar depth of soil and equally fertile, which was not plastered, produced not half as much. About an acre of potatoes, planted in the same field, and plastered broadcast at the same period with the corn, at least doubled the product.

We all know that frequent experiments have been made on wheat, oats, corn and potatoes, at an advanced growth of those products, by sowing plaster, broadcast, over their tops or leaves, without any apparent beneficial effect. I have tried the experiment twice on potatoes and once on corn, without much success: the reason was obvious; the atmosphere was warm, and the earth supplied with a sufficient quantity of moisture.

The main and almost exclusive virtue in plaster is to keep up a moderate degree of warmth, and to supply, through the medium of the leaves, that moisture and fertilizing principle for the support, growth and maturing the grain, which the roots are incapable of affording and extracting from a parched up earth, and the leaves and stalks from a dry, arid atmosphere. Such was the case in July and a part of August with us. Plaster acts very slowly, and almost imperceptibly, even in a drought, on argillaceous or clayey soils, until the succeeding year, when it develops its beneficial effects on clover and other grasses. Plaster does its duty most effectually on all silicious compositions, on sandy, gravelly, and on all soils composed more or less of sand.

On a hasty perusal, a few days since, of the last June number of the Cultivator, I observed a well written production on the subject of lime and plaster as manures, by William Penn Kinzer, of Lancaster Co. Penn. It would require too much space in your useful journal to answer all his objections to the power and effect of plaster. I will answer a few of them as briefly as possible. Mr. Kinzer sowed a small portion of his wheat field with plaster in April, but derived no benefit from it: he says nothing on the subject of the state of the atmosphere or condition of the earth. Plaster affords but little benefit on a well conditioned calcareous soil, which he represents his to be, where a sufficient degree of warmth and moisture prevail, for it is only in their absence that it acts efficiently, even on silicious compositions. He found great benefit, however, from its use with lime. On that point he is unquestionably correct. While the lime acts as a stimulus and fertilizer, neutralizing all the noxious and acidifying principles, and promoting their decomposition, the plaster attracts the requisite moisture for a full development of the power and influence of the lime. Thus positive assertions are sometimes made, condemning in unequivocal terms the power and effect of an agent, without taking into consideration its peculiar nature or composition, deterring others unacquainted with its peculiarly specific and almost exclusive properties, from a trial of its virtues, to the great injury of the public, as well as individual loss. I would refer the reader to Mr. Kinzer's observations on the subject.

JOHN G. GEBHARD.

Claverack, Sept. 21st, 1838.

Live Fences of the Willow.

White-Hall, Va. 27th Sept. 1838.

JUDGE BUEL—Dear Sir—I do not recollect to have seen any thing said in regard to live fences made out of yellow willow: if any thing in the following is worthy your notice, or likely to be of advantage to the numerous readers of your excellent paper you may use it to the best advantage. In our region, say the counties of Frederick, Clark, Warren, Page and Shenandoah, there are many miles of live fence, especially upon the banks of the North and South branches of the Potomack river, made of the branches of the yellow willow. In the month of March they are cut down and trimmed with an axe, say eight or nine feet long, so that cattle cannot well reach the tops and trim them, in which case they do not live well: however they are planted at most all seasons of the year, though the spring is preferable; all sizes are planted, as near the edge of the water as possible, in the spring: at other seasons, when the waters are low, we do not plant so close. About the size of a man's wrist is the best size to live well, but they are often much larger, as well as smaller, and do well: they are generally planted three or four feet apart, the large end of the limb, branch or plant being cut sharp, ready to force in the ground, which is done by means of a Jackson, (as some call it,) made of tough oak, gum or locust, to drive in the ground, say eighteen inches or two feet: this Jackson, as it is called, has a pin through the top, an inch and a fourth or half thick, to draw the Jackson, and an iron socket at the bottom. It is best, perhaps, to have several sizes to suit the limbs. After the Jackson has been drawn, the plants pushed down in the hole firm, two or three hands will make a long string of fence in a day by having two good mauls: the hole is made in less than a minute. After the willows are set it is best to plat in brush of some kind; if you do not, and water should get high soon after planting, they will not stand so well; and another advantage in platting in brush is, sediment and trash settle in behind the willows, make them stand firm, and grow more rapidly. However, some few plant and leave them several years, then cut off the tops and plat the fence, which is not a good plan. A live fence in this way is ready for use as soon as it is platted. We have taken a great many rails and fire wood off of those fences when they get ten or a dozen years old, the growth on water is so quick.

I remain, dear sir, your most obed't servant,

SAM'L M. SPINGLES.

Siberian vs. Italian Spring Wheat.

Utica, September 25, 1838.

MY DEAR SIR—The interest which I feel in relation to agriculture has not abated; nor have I suffered my attention to, or observations upon, the wheat crop to be arrested or diverted by the ill-natured remarks which have been elicited from individuals in Oneida county, where so much Italian seed wheat has been sold. I last year gave the public my experience in regard to the Siberian variety of spring wheat; and I further did that which was not only my privilege but my duty to do, in comparing my own Siberian with the Italian which was cultivated on three farms adjoining my own; which were all the pieces of the kind within my knowledge. Whenever public feeling is to be awakened to this or to any other important object, it is to be expected that the more sordid and bubbling passions will foam over first; but you may rest assured, sir, that more rational feelings, with operative effects, have also been excited: in common with may others I have myself been induced to test the comparative merits of the two varieties. I took much pains to obtain from Rome a fine sample of Italian seed, which, with my own Siberian, I subjected to the following culture:

I had two pieces of ground, of what I considered equal quality as to soil and adaptation to wheat—the one was last year cultivated to peas, with about twenty loads of manure (recent) to the acre; the other was in Siberian wheat, after corn, without manure—the pea ground I considered of the best promise. I concluded to give this lot to the Italian wheat, and give the Siberian the trifling advantage of sowing first as to time upon the other—thus with the like preparation on both, of ground and seed, the two kinds were sowed the first week in May: both grew well—the Siberian was first fit for harvesting—both cut and secured in fine weather—the straw of the Siberian bright and silvery, and berry plump and full—the straw of the Italian lacked lustre and was somewhat rusty, insomuch that the kernel was so shrunk that it will injure both its sale and its price in market.

In my former communication I claimed for the Siberian variety of spring wheat its ability to withstand both rust and smut, to a greater degree than any other kind with which I was acquainted. My experience of the past season sustains its superiority, so far as a single experiment goes, but I do hope that through the medium of your invaluable paper the agricultural public will be furnished with sufficient data to form a correct opinion on this deeply interesting subject. With a market commanding two dollars a bushel for the best of wheat, and ten dollars a barrel for best of flour, shall it be considered obtrusive to urge the wheat crop upon the farmers' notice? Shall I be contradicted when I say that rust and smut have been for nearly half a century the greatest enemies of the wheat crop? And will you impeach my motives (whilst you have not distrusted my statement,) when I tell you that in my four years' experience it has resisted both perfectly? Far be it from me to consider the question as having been settled by the experience of any one individual for a few seasons, but in the absence of other and better testimony let it have its due weight. Respectfully yours,

THOMAS GOODSELL.

The ears are not well filled this season, in either the Siberian or Italian. As we have not thrashed, I am unable to say what will be the comparative yield per shock, or per acre.

Italian and Siberian Wheat—Dutton Corn.

Harmony, August 14th, 1838.

Dear Sir—I procured from Oneida county the Italian and Siberian wheat: the Italian did the best. This season, I procured the early yellow Dutton corn, a sufficient quantity to plant three acres: it proves to be the earliest, and most beautiful corn I ever saw. I have raised 150 bushels for seed, which, I think, will be insufficient to supply the wants in this vicinity. Yours truly,

EDMUND WELLS.

A Profitable Mixed Crop.

Middletown, Monmouth Co. N. J. Oct. 11.

Mr. Buel—Excuse me for troubling you with a few questions. Is the smut on maize of the same nature and habit as the smut on wheat? Does the smut adhere to the grain, and being absorbed by the plant, and circulating through the sap, produce the disease? And do you think the same steeps, used successfully for wheat, will destroy the smut on seed corn? I have been in the habit of selecting seed corn whilst gathering, and leaving some husk on, and tying it for a mark, and throwing it in the wagon with the others, and assorting it at the crib. Some of the smutty corn being thrown in the wagon likewise, impregnates all my seed corn.

I have been in the habit of using fish as a manure, with advantage. Now I have heard it asserted that in New-England, where they have used them many years, they have at length rendered the land barren and unproductive. Some intelligent men with whom I have conversed on the subject, think it not improbable that by the continued use of them, the ground becomes saturated with oil and forms an indecomposable substance, similar to oil paints. What is your opinion in regard to it? Will some of your readers, who know any of the facts in regard to their long continued use, publish that knowledge through your columns? By so doing they will oblige me and others of your readers.

I have some land that I wish to under-drain: but at the depth of eighteen inches it is, in many places, a loose quicksand. Will not the quicksand fill up the drain? How will slabs do for under-drains? Will they rot very fast where they are continually wet?

I have been successful in raising a large crop from a small piece of ground; perhaps it may be useful to state the circumstances. Watermelons having been an uncertain crop, for several seasons past, I determined last spring to plant potatoes amongst mine, so as to be sure of part of a crop. I struck it out both ways eight feet apart for melons, and then split the intermediate spaces both ways for potatoes, (making the hills four feet apart,) which I planted early, putting one large shovel full of manure in the potato hills, and three in the melon hills, and afterwards put three fish to a hill. The drought hurt the potatoes, but benefitted the melons. The piece contained three acres, and produced as follows, viz:

The watermelons,	47 loads, sold for	$352 25
potatoes,	207 loads, sold for	120 37
		3)472 62
Total per acre,..................		157 54

From your constant reader,

THOMAS ROBERTS, Jr.

Remarks—We have not made any observations in regard to the smut in Indian corn—nor seen any remarks of others; and of course do not feel qualified to answer the inquiries of our correspondent in this matter. Quicksand is a serious obstacle to encounter in draining; yet this obstacle, we think, may be overcome, where there is a moderate descent, and a continued run of water, by covering the drain well with sods or straw. Slabs are a worthless material for drains. The suggestion that the use of fish, in manuring lands, ultimately impoverishes them, is new to us; and if such be the case, which we very much question, it must be by accelerating the decomposition and exhaustion of the vegetable matter in the soil. The decay of the latter, particularly when fibrous or woody, is slow; but when brought in contact with animal matter, as fish, which ferments rapidly, its decomposition may be greatly accelerated. But even in this case, nothing would seem to be lost, as the first crops gain what the later ones lose.—*Cond Cult.*

The Crops.

Black-Rock, Sept. 16, 1838.

After all, our boasted wheat crop in west New-York is a small affair. I am told, on threshing, our farmers have not more than half the quantity they expected at harvest. And although the Ohio and Michigan crop is good, it will be so late to market, that flour will be high through the season. Indeed, pretty much all the mills of the country, excepting those at Black Rock [and at Oswego and Rochester] are dry. These cannot fail so long as Lake Erie holds out. The drought with us is terrible. No rain for several weeks; and indeed only half a dozen light showers since the 1st of June. How the country stands it so well I don't know; yet cattle look well, although the pastures are dry and perfectly parched up. Many of our meadows have been burnt over. Oats are light; potatoes not half a crop—turnips nothing; sugar beets and carrots good. Ruta bagas cannot be depended on—they are so subject to fly and insects—wet seasons only do for them with us. Hay was a good crop. I fear our cattle will go into winter quarters poor. And if the drought continues, it will be very difficult to plough for a large wheat sowing this fall, so hard and dry is the ground. L. F. A.

Chinese Corn.

Hallet's Cove, L. I. Sept. 21, 1838.

Mr. Jesse Buel—Sir—I send you four ears of the *Chinese tall prolific or tree corn* (a few grains of which were found in a box of tea some three years ago,) which was given me by a gentleman. It is a new variety, as it strikes off in branches from the stalk, hence its name "*Tree Corn;*" sometimes four, but seldom less than three branches, and bearing an ear at the end of each branch. It grows from eight to ten feet high, produces abundance of fodder, and is a large white flint twelve rowed corn—ears from ten to fourteen inches long. I counted six hundred and sixty grains on some ears. I planted this corn on the 10th of May; it had ears fit for boiling the 10th of July; its produce was much curtailed by the long drought—but notwithstanding, I counted *two thousand one hundred and twenty grains*, the produce of *one stalk*, being upward of two thousand fold. The Dutton, (which is an excellent corn) planted on the same day, on the same field, and received the same quantity of manure, cross-ploughing and hoeing, did not produce one-half: my patch about two hundred hills was examined by Mr. A. Polhemus of Hurlgate-farm, and many more of our neighbors, who all agree that it was something new, and something very superior.

This corn is for sale at the store of G. C. Thorburn, 11 John-street, New-York, and at William Thorburn's, North Market-street, Albany: the price is 25 cents an ear. One ear will plant *one hundred hills*. Now if there is a farmer between Maine and the Rocky-mountains, who would rather give two shillings for two gills of brandy, in preference of his being put in possession of seed for one hundred hills of such corn—he deserves to be fed on suppaan and butter-milk, as long as his little soul and big carcass will hang together. Yours,

GRANT THORBURN.

We received the four ears of corn accompanying the above letter, and thank our old friend for the compliment; we hope this new variety may realize his most sanguine expectations. —*Cond. Cult.*

Common School Libraries.

New-Rochelle, Sept. 26, 1838.

J. Buel, Esq.—Dear Sir—I have just seen the August No. of the Cultivator, and am gratified to notice that you advocate the formation of agricultural schools, and adoption of measures by government to advance the science, and give additional interest to the practical pursuit of this interesting occupation, by better acquaintance with the theory. You do not over-estimate the subject, and I trust the day is not distant when state authorities will bestow attention upon it, and adopt such measures as shall tend to make us an agricultural as well as a commercial and manufacturing people. Then shall we begin to realize the blessings with which a beneficent Providnece has surrounded us in the diversified soil and climate of our favored country.

But the more particular object I have in this communication is, to correct the impressions you entertain in relation to the school library, recently issued under the direction of the American society for the diffusion of useful knowledge. It is admitted that the fifty volumes do not embrace all the topics of general interest, that the committee were desirous they should; and which in their published prospectus they designed to introduce; but the repeated calls upon them "as stated in the introduction to each volume, induced them to issue a selection from existing publications, while they go on *as fast as possible* to complete the plan."

You will understand from the accompanying documents, the general objects of the society, and how prominent a place the subject of agriculture had in the proposed library for schools, independent of one designed to be issued expressly for the farmer whenever the committee shall receive the necessary materials, prepared and adapted to the genius and character of our own country, by practical and scientific men. The difficulties under which the committee have labored can well be compared to the magnitude of the undertaking. At a time when all our citizens were engrossed in their own occupations, and when few had sufficient resources to meet their daily engagements, the committee have gone on with their work, without seeking the pecuniary assistance of the community, and have prepared, principally of standard works, a library for our schools, which has found favor wherever it has been examined, and which I think must commend itself to you. Even when those books shall be included, which the committee promise to add when materials shall be found, and their means be sufficient, the present selection ought to have a place in the library. You are aware of the time, labor and means necessary to prepare a set of books on any given subject, properly adapted to a specific object. How difficult then must be the task of preparing a systematic series of books on agriculture, suited to our soil and climate, when the subject, as you admit, has been so much neglected? Must we, therefore, withhold all aliment from the minds now maturing in our common schools?

The committee do not pretend that the library is by any means complete, but that it is in itself unobjectionable. The undertaking is one of national importance, in which you and other philanthropists may engage, and by a united and wide spread co-operation make this library as comprehensive and useful to the rising population, as the territory over which they wish it to diffuse an influence, is vast and extensive.

A WESTCHESTER FARMER.

Making and Fining Cider.

Ballston, September 20, 1838.

Dear Sir—Agreeable to my promise, I send you an account of my process of making cider.

I grind my apples after they have become mellow, carefully throwing out all that are defective. I stir up my pomace till it becomes red from the action of the air; then press out the juice slowly—put it in casks—bung it up—and immediately place it in the cellar. Before the fermentation commences, I insert a flexible tube (lead pipe I have used) through the bung, and bend the other end into a cup of water or cider placed on the cask near the bung, to allow the carbonic acid gas to escape, and to prevent the oxygen of the air from decomposing the saccharine matter. So soon as the gas ceases bubbling through the cup, the fermentation has ceased; it is then drawn off into clean casks, bunged tight and placed in a cool dark cellar, where it will continue sweet for any length of time. The advantage of this process is, that you preserve the juice perfectly sweet, and you are more sure to draw it off at the right moment after fermentation has ceased. I place it in the cellar to ferment, because the temperature is more uniform, and it is not so liable to be agitated by sudden gusts of air or disturbed by other causes. When fermenting, the lighter particles of pomace are rising, the more heavy settling; and the least touch of the cask will disturb the operation. I use *no ingredient whatever* to make my cider good or to preserve it; and I almost invariably have it of the purest and best quality. Yours most respectfully, W. G. VERPLANCK.

The Wheat Maggot.

New-Scotland, October 9, 1838.

J. Buel, Esq.—Sir—In the October number of the Cultivator you ask for information respecting an insect or worm, which preys upon the wheat crop after it has ripened. I will describe a destroyer which I have seen, which may or may not be the one you allude to. I had five acres of winter wheat on a dry gravelly soil in the summer of 1832, and a few days previous to cutting it, I rubbed in my hand one of the heads, and among the kernels I discovered a greyish worm, about one-eighth of an inch in length, and about the thickness of a cambric needle: it appeared brisk and active, and, like the caterpillar, upon being touched coiled itself immediately up. It resembled a species of grub, though I saw nothing upon it in the form of legs; on examining the kernels in my hand, I found two-thirds of them punctured as with a small needle; the heart mostly eaten out, and they were easily rubbed fine. I looked still farther but saw nothing more of the worm or its work. In the autumn following, when preparing some of the above mentioned wheat for seed, by immersing it in strong pickle, I was not a little surprised to see apparently full and plump kernels, float on the surface, which, on examination, proved to be entirely eaten up, save the shells; and in most of them a small hole was clearly seen. From every two bushels thus immersed, about one quart floated from the above cause.

My wheat the next year was mostly destroyed by the weevil, [grain worm] so I saw nothing of this maggot, as the weevil destroys the grain while in the milky state.

I purchased half a bushel of Italian spring wheat last winter, from Mr. Van Rensselaer, at the Cultivator office, and on the 28th of May last, it was sown; having prepared it by immersion in a strong pickle, and then mixing with it as much quick-lime as could be made to adhere to the grain. It came up well and grew finely, wholly free from weevil, rust or smut. But behold! a few days previous to cutting it, I discovered one, and only one, of the same species of little grey worms. Just three months from the day it was sown, it was threshed, and yielded about as ten from one. The soil is not a right one for wheat, being too gravelly; and was shaded by woods on the north, south and west.

Before I lay down my pen, I must just remark, with regard to pickling and liming seed grain, that I believe it should be strictly adhered to, as I have practised it upon all kinds of grain, except peas and buckwheat, and can speak of its benefits to every kind. Yours with respect,

W. MURPHY.

Rohan Potato.

Oxford, *Ct*. *Oct*. 1, 1838.

Dear Sir—I planted, on the 26th of April last, two tubers of the Rohan potato which weighed 13 oz. on a dry loam.

I dug the crop on the 24 Sept. which measured two and a half bushels, and weighed 144 lbs. or more than 160 per cent, notwithstanding the drought. Other varieties on similar soil were not more than half an ordinary crop.

The Rohans are but little known, and will probably command a good price for a year or two; and unless some description of them is given in the Cultivator, there will probably be as many kinds palmed upon the public as there have been of Dutton corn.

My seed, which I had of your neighbor Thorburn, was of an oblong or kidney shape; but on digging the crop I found various shapes, round, kidney, and, as is generally termed, snagged.

On offering some of the kidney shaped ones for a premium at the horticultural fair at New-Haven, they were objected to by some, as not being Rohans on account of their shape. Very respectfully yours,

ALFRED HARGER.

The Grub—Ruta Baga.

Poughkeepsie, *Oct*. 16, 1838.

J. Buel, Esq.—Dear Sir—Being a subscriber to the Cultivator, I take the liberty of stating to you a few facts with regard to some of my crops this season. I observed in one of the spring numbers of the Cultivator, that salt petre was a preventive for the grub worm eating corn, by making a pickle, and soaking twelve hours before planting. I did so, as per order; and planted a field of seventeen acres, and at the proper time the grubs came along, and it appears the flavor of the salt petre just suited their taste, for they cleared ten and a half acres of my corn-field almost entirely; the remaining six and a half acres, I planted some of it in three times, and have now about one-third of an average crop. I would have been better off if Mr. Grub had taken the whole, as I ploughed up the ten and a half acres and sowed three and one-fourth bushels of buckwheat, from which I have 300 bushels of very fine buckwheat, and sold it at 75 cents per bushel, and I am certain there is 50 bushels lost on the field, as it had all to be mowed, as it was all lodged and could not be cradled. Therefore I think it will take more men than ever I have seen, to convince me that salt petre will stop the grub from eating corn.

I have succeeded very well these four years in growing the ruta baga. I have had each year about 600 bushels to the acre; this season the drought and the fly injured my turnips some, but I will have an average crop still. I consider it a very valuable crop, as I have sold them at from four shillings to six shillings per bushel, and in the spring, my horses, oxen, cows, sheep, hogs, and even the poultry eat them and do well on them, and they are remarkably good for horses that have got the heaves, and also a good preventive for that disease. My method of cultivating the ruta baga is the same that is practised in Scotland. I plough the ground in April, and on the 20th of June harrow it, and cross-plough and harrow until the ground is perfectly fine. I then draw my drills with the plough two and a half feet from centre to centre; I then take a one-horse cart or wagon, but a cart is best, as the drills are injured with so many wheels turning on them; I put manure in each drill as for potatoes; then I take the plough and split the drills right and left; then I take a light roller long enough to reach over two drills, with one horse, and roll the tops of the drills once over; then I take the drill barrow and sow the seed; then I pass the roller once over the seed; when the turnips are up about two weeks, I go through with a hoe and thin them, leaving them eight inches apart, and in two weeks more, I plough between the rows; I then go through with the hoe and clean the tops of the drills of all weeds and grass and in about 3 weeks more I plough them again; then in the fall I take a scythe and cut as many tops as the stock will use in one day, and so until all the tops are used; then take a dung hook and drag out all the turnips, make pits that will hold about six loads; make the pit two feet wide and two feet deep, and build them up like a roof, the more above the ground the better, as they will not keep if they are warm; cover with a little straw to prevent the earth from going among the turnips; for each pit make three little flues for ventilators; then put on from four to five inches of earth, clapped well down with the spade. The turnips will keep better in this way than in a cellar, as a cellar is too warm.

Please excuse me for troubling you with this long story, but I have seen this crop managed in this way in Scotland, and never failed, forty years ago. I remain, dear sir, your serv't,

JOHN BODDEN.

EXTRACTS.

The Philosophy of Vegetation.

[*From the Genesee Farmer*.]

Perhaps there are few subjects of so much interest to the farmer as a proper understanding of the causes and agents of vegetable nutrition. The economical application of manures, the propriety of their use, the value of a system of rotation in crops—in short the whole philosophy and practice of farming—may be said to be depending on this point. Is there but one substance in nature that constitutes the proper food of plants? or are they endowed with omnivorous powers, and capable of finding food in all things presented to them? If there is but one kind of food, what is that one?—and if there are many, what is their state when appropriated by the plants? These are a few of the subjects that enter into a consideration of the food of plants; and the opinions of writers on vegetable physiology have been as various and conflicting as the substances which chemical analysis has detected in plants have been numerous.

Some have maintained that the actual nourishment was derived from the air: some that water alone constituted the food of plants; others have asserted that the growth was owing to a single substance, and that the earths which are present in plants, as well as most of the salts, are to be considered as merely accidental, not being necessary to the formation or growth of the vegetable: the only substance which all are agreed in considering absolutely indispensable, since it is a large and apparently essential part of every plant, is carbon. If the plant derives its support from the air, then the carbonic gas which exists in it must be the source of supply: if taken into circulation by the roots, then the carbon must exist in some soluble form, since the greatest chemical skill has never been able to induce a plant to take up the minutest portion of insoluble carbon, or detect its presence as an operation of nature.

Amidst these conflicting sentiments, adverse and contradictory as they may at first seem, we think that the opinions of men of science are verging to an agreement on one or two of the most essential points; and what we consider as of quite as much consequence, these opinions very nearly coincide with the actual experience of the farmer, and give a strong support to the modern theories and practice of agriculture.

We believe that Klaproth was the first to discover and announce to the world the existence of a peculiar substance, which he considered of importance to vegetable organization from its analysis, and which, from his first finding it in the bark of the elm, he denominated ulmin. Braconnet continued the investigation commenced by Klaproth, and found there were few substances of vegetable origin in which ulmin did not exist, tracing it in considerable quantities in sawdust, starch, sugar, seeds; and indeed in nearly all plants it was present. Berzelius, the great Swedish chemist, embraced it in his researches, and extending them to the soil, found that it existed in the earth in abundance, as well as in the bark and ligneous substance of trees. From its presence in the earth, and the probability that it was from thence that plants derived it, Berzelius distinguished it by the name of *geine*, a word derived from the Greek word signifying the earth. Sprengel and Bouillay have discovered that it is a leading and efficient principle in vegetable and animal manures, and hence they have denominated it *humine*, a name by which it has been most generally known, though scientific men are appearing to incline to return to the nomenclature of Berzelius. The justly celebrated chemist and observer, Raspail, in his late work on Organic Chemistry, translated by Dr. Henderson, denies the existence of *geine*, or *humine* as a proximate principle in soils, and says, "it will be easy to see that all these phenomena, (described by Berzelius, Sprengel and others,) apparently so varied, which have given room for the discovery of so many substances analagous to ulmin in their nature, are essentially nothing but a development of carbon." The name, however, we consider of mere secondary importance, and whether it is called *ulmin*, or *humine*, or *geine*, or *carbon*, it cannot effect the results which seem to flow from the substance and render it one of the most important agents in vegetable nutrition, if not the only one yet known.

Geine, says Professor Hitchcock, in his late admirable Report on the Economical Geology of Massachusetts, "when wet, is a gelatinous mass, which on drying, becomes of a deep brown, or almost black colour, without taste or smell, and almost insoluble in water; and, therefore, in this state, incapable of being absorbed by the roots of plants. Yet after the action of alkalis upon it, it assumes the character of an acid, and unites with ammonia, potassa, lime, alumina, &c. and forms a class of bodies called *geate*, most of which are soluble in water, and therefore capable of being taken up by the plants; and it is in the state of *geates* that this substance, for the most part, exists in soils."

Silica, alumina, lime, magnesia, oxide of iron, potash, soda, and sulphuric and phosphoric acids, may be considered the inorganic principles of vegetables, and analysis detects their presence in the most of them; hence they will be found the constituents of all soils, for the most part existing as salts—for instance, carbonate of lime, sulphate of lime, muriate of lime, phosphate of lime, &c. Neither the earths nor the salts can be considered the proper food of plants, as both these may be present, and yet a weak or imperfect vegetation, or none at all, be the result. But if the combination of these salts with humus or geine has taken place, then, in connexion with the earths, vegetation will be vigorous, and the proper functions of plants fully developed. In the language of Dr. Dana, it would seem then "that the earths are the plates, the salts the seasoning, the geine the food of plants."

The 'Soluble Vegetable Extract,' of Davy and Chaptal, produced from carbonaceous mould, is the soluble *geine* of Berzelius, and the insoluble matter of the mold spoken of by Chaptal would seem to be the insoluble geine or humus of Berzelius and Sprengel. Geine is, therefore, the decomposed organic matter in the soil. When the result of recent decomposition, it is abundantly soluble in water; the action of the atmosphere converts this soluble matter into solid humus or geine, 'still partially soluble in water, and wholly soluble in alkali.' Soluble geine, and in this state only does it become the food of plants, acts neither as acid nor alkali. It is converted into a substance having acid properties by the action of alkali, and in this state combines with earths, alkalies and oxides, forming neutral salts, soluble in water, such as magnesia, lime, &c. and thus matter insoluble of itself is prepared for the food and nutrition of plants. It appears to have been satisfactorily established by late chemical researches, that this substance forms the nourishing basis of all soils, and that they are fertile or infertile exactly in proportion to the soluble geine they contain, or the application of materials capable of converting the insoluble into that which is soluble.

If there are any facts certain in agriculture, it is, that a soil composed chiefly of one of the earths, either sand, lime, or clay; or one that contains an excess of salts, as pure manures; are always barren. Plants may indeed exist to a limited extent, but they will be weak and without fruit. To these earths add geine, and a perfect healthy vegetation will be the result. The great essentials of vegetation, then, are the earths, salts, and geine, and their degree of fertility will mainly depend on the proportion with which the last is mixed with the first.

Every discovery in experimental philosophy—every advance in vegetable chemistry, seems to render more clear the great truth, that nature's works, though apparently complex, are carried on in the simplest manner, and with the fewest possible agents. The slight shades of difference found to exist in the constituents of most dissimilar substances, such as starch, lignin, sugar, and some of the acids, prove that slight causes produce powerful modifications of matter, and render it probable that the original kinds of matter are less numerous than have been usually supposed. All investigations point to an agency that pervades all the forms of matter, and by an arrangement of atoms consequent on vitality produces all the varied forms of vegetable and animal nature. This agent, under the name of caloric, galvanism, or electro magnetism, is constantly at work modifying, changing, combining, decomposing and arranging. To it we owe aggregation and cohesion—to its subtile and diffusive energy, all growth and circulation—and may it not be considered as certain that the earths and salts are a magnificent voltaic battery, ever ready for action when moistened with water, and thus reviving the dormant vitality of the seeds submitted to its influence. But though this vitality may be revived, and the slumbering energy of this germ of the future vegetable be restored to activity, it is clear that the circulation will produce little or no effects in inducing growth, unless matter suitable for absorption and after-deposition, is provided for the newly awakened energies and action. This is furnished by geine, and is presented in a state the most suitable for the circulating juices of the plant. Taken up by the roots, or absorbed from the air, it is converted into lignin or woody substance by deposition and æration, and thus becomes a new plant, prepared to run its course of growth, maturity and decay.

Taking this simple, and we think philosophical view of the subject, the reasons of many farming processes, hitherto but little understood, are made more plain; and various improvements suggested and made practicable. If a soil on analysis contains an undue proportion of any one of the earths, the evil can be remedied by combining them in the proper manner, by adding what is deficient until the balance is restored. But the fact, that the earths themselves, uncombined with salts or geine, are never fertile, and that all the combinations of which they are capable, can never be made to support vegetation, should not be lost sight of. Some soils, from the proportion of the earths found in them, are more friable and easier to work than others; and some combinations are proved to be more suitable for the union with salts necessary to the excitement of voltaic or galvanic agency and the consequent vitality and circulation of plants; but alone, no possible modification or combination can make what is called a fertile soil. Were we to name for comparison the agents and the several parts they perform in the process of vegetation, we would call the *earths* the plates of the galvanic battery, inert while dry, or not subjected to exciting causes; the salts by their solubility furnishing the acids, such as carbonic, sulphuric, phosphoric, necessary to rouse the battery to action; and when this is done, humus or geine offers the only matter that can be taken into circulation and constitute (properly speaking) the food of plants.

According to the modern investigations of science, every particle of matter is pervaded by this universal agent, and requires only the aid of moisture to its greater or less development; the intervention of the fluid serving as a conducting power between the several particles. Pure water is the weakest exciting power yet known, but at the same time the most durable. This is beautifully exemplified in the experiments of Mr. Crosse, who uses only water for the exciting power of his batteries when he requires their uninterrupted action for weeks or months, the slow continued excitement being more favorable to the development of animal life, or metallic or mineral crystallization, than one more powerful, but of shorter duration. This action of water shows why water alone, applied to the earths and through them to vegetables, has so feeble and tedious an operation on their development. On the contrary, if the acids are supplied, and this is done in a multitude of ways, the action becomes at once vigorous; and connected with a proper supply of food, vegetation will be rapid and abundant.

This theory of vegetable nutrition explains, in our opinion, far more satisfactorily than any other, the mode in which manures, vegetable, animal and mineral, produce their effect on vegetation, and stimulate its growth. According to Chaptal, the different substances afforded by animals, and useful as manure, including all their secretions, are, "gelatine, fibrine, mucus, fat, albumen, urea, uric and phosphoric acids, and some of the muriates or salts." Here, it will be seen at a glance, are a multitude of exciting and nutritive causes mingled, and when combined, as animal manures usually are, with vegetables decomposed, the available geine is considerably increased. The liquid manures found so powerful in Flanders, and the use of which is such a marked feature of the excellent Flemish husbandry, are, it is well known, mostly composed of the urine of animals. The analysis of urine by Mr. Brandt discloses the cause of this efficiency.

Water,	65
Phosphate of lime,	5
Muriate of Potash and ammonia,	15
Sulphate of Potash,	6
Carbonate of Potash and ammonia,	4
Urea,	5
	100

A more active combination could scarcely have been devised than this analysis shows such manures to be; and though Fourcroy and Berzelius slightly vary the constituents, their analysis does not materially alter or impair its efficiency. Of the above animal ingredients, we will select but one to illustrate our theory, as it is one respecting the efficiency of which as a manure there can be no doubt, and which is daily coming into more general use—we allude to phosphate of lime or bone dust.

Bones, as a whole, contain about equal quantities of phosphate and gelatine. The harder and more compact the bone, the greater the amount of phosphate, and the less the proportion of gelatine. The bones of the ox contain from 50 to 55 per cent. of gelatine; those of the horse only from 36 to 40; those of the hog from 48 to 50; and the bones of the legs and feet of the deer, elk, roebuck, and hare, give an analysis from 80 to 90 per cent of phosphate. All the roots, such as beets, carrots, &c. and the grains, such as wheat, corn, &c. contain considerable quantities of this phosphate; and its presence would seem to be of much importance in the vegetable and animal economy. When bone dust is deposited in the ground, it speedily undergoes decomposition, and the principal ingredients in its composition are set at liberty to form new combinations, and perform a new part in the great circle of nature's revolutions. The phosphoric acid leaves the lime, and as in all its forms of existence it is one of the most exciting agents, its application to the earths is almost as immediate as the dip of the chemist's plates into the galvanic trough. The lime set free is, by the absence of the neutralizing acid, perfectly caustic, and seizing at once on whatever geine is found in the soil renders it soluble, and thus fit for immediate use by the plants while in their excited state of action. Can it be wondered at then, that bone dust should be efficacious, or that its effect on vegetation should be almost instantaneous? It may be further remarked, that bone dust applied to very dry or very wet land, loses much of its efficiency; a reason for which may be found in the fact, that in the first instance the ordinary voltaic agent is but imperfectly supplied, and in the last, the acid is so diluted as to become but little superior to water itself.

The efficiency of carbonate of lime as it is generally applied to soils, is to be accounted for on the same principles. It differs, however, in this respect; in the phosphate the acid is set at liberty in the soil, in the carbonate it is driven off by burning. Like the phosphate, the lime is at liberty to unite with and render soluble, all the insoluble geine or vegetable matter in the soil, but unlike that it furnishes no acid to stimulate the voltaic agency to more vigorous exertions. Its effects, though certain, and most beneficial, are not so immediate as those of the phosphate. We may say, that by the application of common lime, the food of plants is *cooked* for their use; by the phosphate, it is not only cooked, but they are excited to devour it. The better the operation of lime in all its forms is understood, the more highly will it be prized and its use the more widely extended.

This theory of the nutrition of plants by voltaic agency, most happily explains the manner in which such small quantities of the salts of lime produce such astonishing effects on vegetation. Every experimental chemist knows what effect the combination of a few drops of acid with the water of his galvanic trough will have on his battery; and the application of lime to our battery of nature, when under proper circumstances, is equally effectual; —nay it does more, for the application of the acid by the chemist only excites his instrument to activity, while the lime furnished the earth by the farmer not only excites the action, but furnishes the material upon which that action can profitably be exerted. All persons acquainted with the use of lime are agreed that it produces little or no effect, except by mechanical division, only on lands that contain animal or vegetable matter that requires decomposition, a decisive proof that lime of itself does not constitute the food of the plant. But let a soil deficient in lime, and containing the food of plants, be furnished with the smallest quantity, and, unless rendered inactive by perfect dryness, or excessive moisture, its effects will be observable at once. Even the small quantity that adheres to wheat, when steeped and rolled in lime, produces a sensible effect on the vigor and rapidity of the shoot. So too with the sulphate of lime, which, at the rate of only one or two bushels an acre, produces such an effect on many kinds of vegetation.

If our notions of vegetable nutrition are correct, all soils will be fertile that contain lime, and geine or humus; and the object of the analysis of soils will be directed to the determination of these two points. The sand and the clay present in any soil can be known without difficulty. Every farmer knows whether his soil is adhesive, retentive of moisture, or, in other words, convertible into mortar by moisture and the operations of agriculture; or whether it is dry, porous, easily parting with water, and liable to leach; and he knows too that a combination of these soils will materially benefit, and remedy the evils of both. But he has not hitherto been able to determine the best applications to give fertility to his soil, or ascertain whether the defect was the want of lime or vegetable matter; and the methods of analysis proposed by Davy, Chaptal, Beck, and others, are too complicated and nice for his purpose.

This difficulty we imagine is now in a great measure overcome, and a method of analysis discovered, by which any farmer, with little time and expense, may determine the quantity of vegetable nutriment that exists in his soils, whether it is soluble or insoluble, and whether lime is present, or requires to be applied to promote decomposition and vegetation. Dr. Dana of Massachusetts, who has long been occupied in chemical investigations, connected with manufactures and agriculture, has lately given the following directions for ascertaining the geine in the soil, and the lime. It will be seen the process is very simple, and can scarcely fail of being effectual.—We quote from Prof. Hitchcock's Report:

"1. Sift the soil through a fine sieve. Take the fine part, and bake it just up to browning paper.

"2. Boil 100 grains of the baked soils, with 50 grains of pearlashes, saleratus, or carbonate of soda in 4 ounces of water, for half an hour; let it settle; decant the clear; wash the grounds with four ounces of boiling water;—throw all on a weighed filter previously dried; wash till colourless water returns. Mix all these liquors. It is a brown solution of all the soluble geine. All the sulphates have been converted into carbonates, and with all the phosphates are on the filter. Dry that, therefore, with its contents at the same heat as before. Weigh—the loss is *soluble geine.*"

For the lime:

"Replace on a funnel the filter and its earthy contents; wash with 2 drams of muriatic acid diluted with 3 times its bulk of cold water. Wash till tasteless. The carbonate and phosphate of lime will be dissolved, the alumina scarcely touched. We may estimate all as salts of lime. Evaporate the muriatic solution to dryness, weigh, and dissolve in boiling water. The insoluble part will be phosphate of lime. Weigh again—the loss is sulphate of lime."

To ascertain whether the residuum contains *insoluble geine:*

"Test it by burning a small quantity on a hot shovel—if the odor of burning peat is given off, the presence of insoluble geine is indicated. *Calcine* and filter. The loss in weight will give the insoluble geine."

Science of Gardening.—*Continued.*

[*From the Alphabet of Gardening.*]

GARDEN-PHYSICS.

The first topic to which I request attention under this head, is the direction in which plants and their several parts, naturally grow; a thing of important consideration in all the varieties of training, as much injury may be done by opposing natural laws, while much benefit may accrue from turning these artificially to advantage.

DIRECTION OF PLANTS.

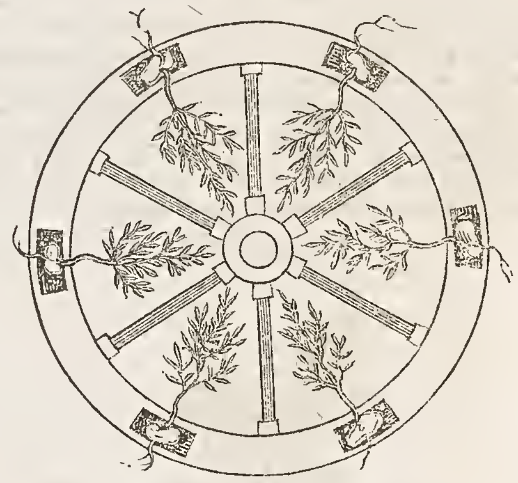
On going up a steep hill, we find ourselves forced to stoop forwards by an invisible force, as if it were pulling the body down to the slope. It is this force which causes a stone thrown up in the air to fall down again, and which causes a soap bubble and a balloon to rise up above the ground by pulling down from above them the heavier air, which, being very moveable, will not rest on the top of a light body, any more (and for the same reason) than a sheet of water would rest on the top of a cork.

It is inferred from certain ingenious experiments, that it is this same force which causes most plants to grow upright with their roots more or less perpendicular to the stem. Dobereiner, a celebrated German writer, proved by experiments, that the same species of plants will rise higher in condensed than in rarified air, and hence, on high mountains, trees become dwarfish; a circumstance also in part caused by the light being there more bright and intense.

On the supposition, that the roots of plants descend into the soil either from their dislike to light, or their natural propensity to extend themselves in search of nourishment, Dr. Grew, and recently M. Dutrochet, found, that when kidney beans were placed in a suspended box, with air above them, and holes below to admit light, they sent their roots down through the holes into the light, and not into the earth in the box.

M. Dutrochet also repeated the ingenious experiment of Mr. T. A. Knight, of planting kidney beans in moistened moss, and placing them on wheels, revolving both vertically and horizontally, by a shaft from a water mill. The beans germinated well, and the result was curious. The vertical wheel, which went at the rate of 150 turns in a minute, caused all the roots to point outwards, precisely in the direction of the spokes of the wheel, while the stems pointed as invariably towards the centre, where, in the end, they all met.

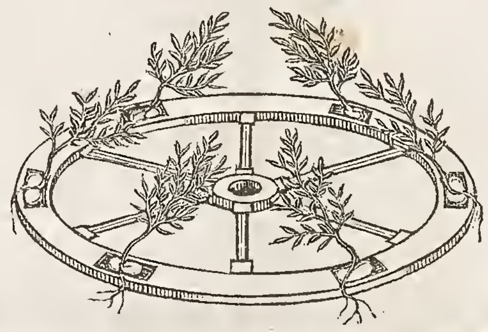
[Fig. No. 56]



Mr. Knight's vertical wheel, with germinating beans.

On the horizontal wheel, again, which went at the rate of 250 turns in the minute, the roots, instead of running directly downwards, as they would have done if at rest, pointed in a slanting direction outwards, while the stems pointed aslant inwards, forming a cone at some distance above the centre.

[Fig. No. 57.]



Mr. Knight's horizontal wheel, with germinating beans.

Lord Kames mentions a plane tree growing on the high wall of a ruin, which sent a root down along the wall to the ground; a circumstance easily accounted for on the same principle, though it has been adduced as a proof of instinct, if not of reason, in the tree itself.

From these facts, it is evident that the number of tall plants, such as Jerusalem artichokes, on a particular piece of ground, cannot be increased, as some have fancied, by making the surface irregular; nor can more trees rise on a small hill than on a spot equal to its base, though this will not apply to strawberries, New-Zealand spinach, and other creeping or spreading plants.

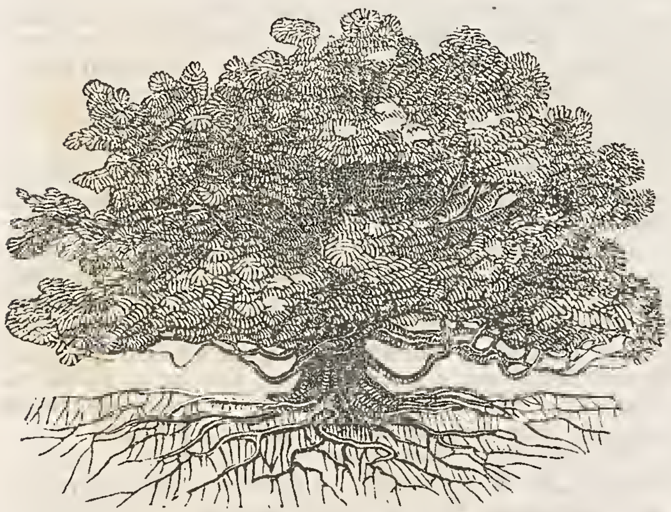
EXPOSURE AND SHELTER.

The degree of light, and of exposure, has a great mechanical effect on plants. In the interior of forests and crowded orchards, the wind produces much less effect than on solitary trees in a garden or park. When crowded, the tops push up into the light above, and not being agitated by the wind, their trunks do not thicken, or become stunted, to prevent the blast making a greater pull against the roots.

On the other hand, when standing in an open situation, trees, being freely exposed to every storm, give every advantage to its violence, by the wide-spreading of their branches.

In accordance with this, solitary trees become greatly larger than those which are crowded, while their system of roots is always proportional to the branches, in order to afford a heavier ballast and a stronger anchorage for counteracting the great spread of sail displayed in the wider expansion of the branches. The same is true of all or most garden plants, which extend in proportion to their room. Hence the necessity of wide planting when it is required to have plants with large spreading heads, as in the instance of New-Zealand spinach; and on the other hand of planting closely when plants are required to be tall, and at the same time slender, a case which more rarely occurs than the other.

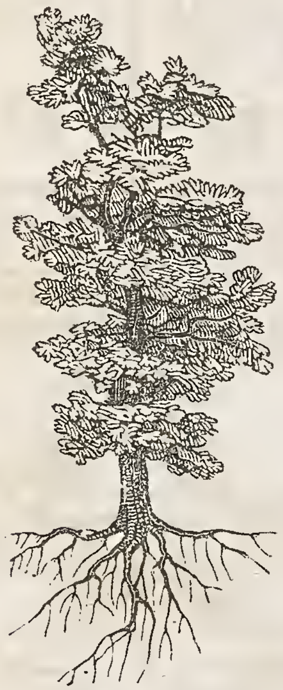
[Fig. No. 58.]



A tree taken from an open exposure to show that the roots spread out proportionally with the branches.

Recent writers on botany have endeavored to show that the tapering tuber of the carrot, the beet, and other simpler plants, are not properly roots, or at least that they have more the characteristics of stems than of roots; in other words, as every plant grows in two directions, one downwards, the other upwards, the spindle-formed tuber of the carrot is alleged to belong to the upper or ascending portion of the plant, rather than to the downward or descending portion. Independent of structure, however, this would appear to be equally rational as to allege that a man's feet belong to the upper portion of his body, but it appears to be correct enough to say that the partly horizontal portions of the iris, though under ground, are not roots but stems; and it must be very obvious that the creeping runners of strawberries are not stems.

[Fig. No. 59.]



A tree taken from a crowded plantation to show that the roots are equally small with the branches.

Weak stems which cannot rise high in a perpendicular direction by their own rigidity, are furnished with several means for effecting this. Some straggle up irregularly amongst other thick-growing plants, as the bramble and bitter-sweet; others, like the hop, the kidney-bean and convolvulus, twine closely around others stronger than themselves, and when they cannot meet with such, several shoots will twine around each other, to give mutual support.

It is important to remark, that different species, in twining for support, follow different laws, one going from right to left, of which there are twenty genera, and another from left to right, of which there are ten genera. A hop-plant, for instance, directs its course round a pole with the sun; but if untwisted and forced to take an opposite direction, it will injure or perhaps kill it.—If a honey-suckle do not meet with support, it twists into a spiral from right to left. It is of importance to attend to these circumstances in training.

MECHANICAL TEXTURE OF SOILS.

Though it has been stated above, that the roots, at least of trees, are generally proportional in extent to the branches, this must be taken with some limitation, inasmuch as it will in part depend upon the texture of the soil. The perpendicular extent of roots, for example, is greatly influenced by the looseness or compactness of the soil; and hence Du Hamel found the tap-root of an oak, which had been sown in a rich deep soil, to be four feet in length, while the stem rose only six inches high. Carrots and similar deep penetrating roots, when they meet with a stiff soil, not easily divisible, are not only dwarfed, but split into branches or twisted into a spiral. When certain roots, also, such as those of timothy grass, are planted in the moist soil natural to the plant, they are fibrous; but when on the top of a dry wall, they become tuberculated; for the purpose, it would appear, of laying up a store of nourishment in case of accidental drought. An alder root was found amongst gravel, marked all over with the contour of small stones.

Since then the mere texture of a soil, independently of the food of plants which it contains, produces such remarkable effects, it must be of great importance for the gardener to attend to this circumstance.

CIRCULATION OF WATER IN SOILS.

It is no less necessary for the due nourishment of plants, that the water by which soils are moistened have a proper movement or circulation, than it is for the animal food, when digested, to pass through the stomach and have a proper movement through the bowels. In the case of the animal, when this movement in the bowels is too rapid, as in cholera, the food is hurried off before it can be conveyed into blood, and when it is too slow, as in costiveness, the mouths of the minute tubes are pressed upon and obstructed, so that the food* cannot obtain admission. It is much the same with plants, when the soil is so loose and porous as not to retain moisture, or so stiff and compact as not to allow what water it imbibes to circulate. In the latter case, indeed, plants are more precisely like animals affected with costiveness, in that the rejections of the digested food are retained so near the mouths of the nutrient vessels, as to greatly hinder their getting at the proper materials. The difference in plants arises from their having to lengthen their rootlets to get beyond the rejections thrown out, which they obviously cannot do in a stiff hard soil. Even independently of having thus to continue their roots amidst a mass of such rejections, the water, in consequence of stagnating, and of course preventing a fresh supply from above, becomes soon exhausted of the nutritive materials with which it may have at first been mixed.

This is not mere theory, as some may be apt to consider it; for it has been proved by numerous facts, that the most fertile soils are those which are so compounded so as to admit of the greatest, most minute, and most immediate distribution, diffusion and circulation of water, or rather moisture; for when water is found in such portions as to be distinguished from the soil which it moistens, this will form, in most points of view a watery and bad soil.

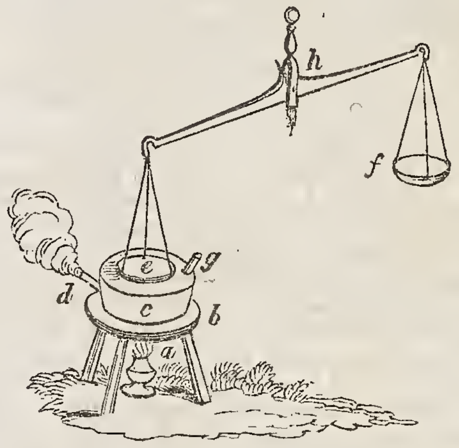
The chief causes of the circulation of water may be traced to the principle which makes a stream run down a slope. When rain accordingly falls on the level surface of a loose porous soil, it will sink into it; and if this, instead of being level, is sloping, the water will both sink partly into the soil, and also move slowly through it towards the bottom of the slope. If the soil is so loose to any depth as to cause this water to drain nearly all away, the first warm day will expand the water nearest the surface into vapour, and raise it into the air; and as soon as by this means the surface becomes dry, the moisture below will gradually rise, in the same way as water may be seen to rise into a bit of blotting paper, or a piece of lump sugar.

It hence becomes obvious, that though the surface soil be sufficiently porous to permit the due circulation of water both upwards and downwards, if the under soil at some little depth, (say from less than a foot to two feet or more,) be a stiff clay, a hard marl, or a level rock of any kind, the rain water, instead of circulating wholesomely, will settle there, from being out of the reach of the sun's influence to raise it; and in the case of the level rock, having no declivity to run off by. It is in such cases that draining becomes useful; or, where it can be effected, forming a gentle slope of the whole surface, which would farther operate on the circulation of the water by obtaining a more powerful influence of the sun, and thereby increasing the heat. The fancy stated in books, that the runs of earth-worms or dew-worms are important for draining off water, is without any foundation.

TESTS OF THE TEXTURE OF SOILS.

One of the best methods of ascertaining the capability of any soil, to take up and retain moisture, is that described by Mr. C. Johnson, for which purpose he employs the following apparatus.

[Fig. No. 60.]



Analysis of soils. *a* a small lamp; *b*. a stool, with a hole in the seat for receiving *c*, a shallow tin vessel, closely covered, but having a pipe, *d*, for the escape of steam; *h*, a pair of accurate scales, such as are used by apothecaries and goldsmiths.

In order to employ this apparatus, put a small quantity of the soil to be tried upon the top of the tin vessel, in which water is kept briskly boiling for about half an hour, so as to thoroughly dry the soil by expelling its moisture. Take ten grains accurately weighed of this dried soil, and add to it, by means of a quill, a drop or two of pure water; if distilled water can be had, so much the better. Weigh the whole a second time, which will now be a few grains above ten. Take out the weight of the water from the scale, leaving in the weight of the dried soil, and suspend the beam, so that the scale *e* may rest on the lid of the tin vessel, the water in which is still kept boiling; then with a stop watch note the exact time which the added water takes to evaporate, as will be shown by the beam of the balance becoming level. Mr. C. Johnson found, that soils requiring less than twenty-five, or more than fifty minutes, to evaporate the added water, and bring the balance to a level, were always proportionately unproductive; the first, from having too much flinty sand, and consequently no texture fitted for retaining water; and the second, from having too much clay, and consequently too few interstices to allow the water to escape.

Rich soil, treated in this way, required thirty-two minutes to bring the beam to a level; chalk twenty-nine minutes, poor flinty soil, twenty-three minutes, and gypsum, only eighteen minutes.

A very fertile soil from Ormiston, Haddingtonshire, containing, in one thousand parts, more than half of finely divided materials, among which were eleven parts of limestone soil, and nine parts of vegetable principles, when dried in a similar way, gained eighteen grains in an hour, by exposure to moist air, at the heat of sixty-two degrees Fahrenheit; while 1000 parts of a barren soil, from Bagshot Heath, gained only three grains in the same time.

Mr. C. Johnson farther found that one hundred parts of burnt clay, when exposed in a dry state for three hours to air saturated with moisture at sixty-eight degrees, took up twenty nine parts of water; that gypsum, in similar circumstances, took up only nine parts; and chalk only four parts.

Another method of testing the texture of soils is, by taking what is termed their specific gravity; that is comparing what they weigh in air with what they weigh in water. Sufficient accuracy for practical purposes may be obtained by drying two different soils, at an equal distance from a fire, or in an oven, at the same time, and then weighing in the air a pound of each in a thin bladder with a few holes near its top, or neck. When the weight has thus been obtained in the air, the bladder may be put into water, letting it sink low enough to permit the water to enter through the holes in the neck, in order to mix with the dried specimen of the soil. The weight in water, divided by the difference of the two weights, will be the specific gravity, and the less this is, the greater will be the capacity of the soil to take up and retain water. Muschenbroek thus found rich garden mould to be 1630 compared to 1000 of water, and Fabroni found a barren sand to be 2210 compared to 1000 of water.

Or fill a wide necked pint or quart bottle half full with water, and add the soil to be tried till the water rises to the brim. Then if the bottle can contain one pound of water, and gains half a pound additional when filled in this way, half with water and half with soil, the soil thus tried will be twice as heavy as water, and its specific gravity will be two. If it only gain a quarter of a pound, its specific gravity will only be one.

M. Giobert ascertained that a pound of fertile soil contained, of flinty sand, about 4400 grains, of clay about 600 grains, of lime about 400, besides seventy of water, and about twenty-five grains of inflammable materials, chiefly carbon. On a comparative trial of a barren soil, M. Giobert found that a pound weight contained about 3000 grains of flinty sand, about 600 grains of clay, about 400 grains of lime, and little or no inflammable materials. Mr. Grisenthwaite directs an equal portion of two soils perfectly dry, to be introduced into two tall glasses, in the midst of each of which a glass funnel has been previously placed. The soils are to be put in so as to retain, as nearly as possible, their natural state when in the ground, and are consequently not to be too much pressed down. When this has been done, water is to be poured very gradually into each of the funnels, and it will rise up as it does in a piece of lump sugar into the dry soil, as may be seen through the glass. The more rapidly the water is seen to rise the better will be the texture of the soil.

---

* Technically, *Chyle.*

I shall next turn the attention of the beginner to the changes which food, taken up by the spongelets, or suckers, of roots, undergoes in the different parts of the interior of the plant, a subject which is usually termed *physiology*, though the original meaning of this word is merely a "discourse or treatise on nature." As I believe the term is well understood, I shall employ it here.

A Table

For foretelling the Weather throughout all the Lunations of each year, forever.

This table and the accompanying remarks are the result of many years actual observation, the whole being constructed on a due consideration of the attraction of the sun and moon, in their several positions respecting the earth, and will, by a simple inspection, show the observer what kind of weather will most probably follow the entrance of the moon into any of its quarters, and that so near the truth as to be seldom or never found to fail.

MOON. If the new moon, first quarter, full moon, or last quarter, happens TIME OF CHANGE.	IN SUMMER.	IN WINTER.
Between midnight and 2 in the morning, ...	Fair.	Hard frost, unless the wind be S. or W.
— 2 and 4 morning, ...	Cold, with frequent showers.	Snow and stormy.
— 4 and 6 "	Rain.	Rain.
— 6 and 8 "	Wind and rain.	Stormy.
— 8 and 10 "	Changeable.	Cold rain, if wind be W. Snow if E.
— 10 and 12 "	Frequent showers. ...	Cold and high wind.
At 12 o'clock at noon and 2 P. M.	Very rainy.	Snow or rain.
Between 2 and 4 afternoon,	Changeable.	Fair and mild.
— 4 and 6 "	Fair.	Fair.
— 6 and 8 "	Fair, if wind N. W. Rainy if wind S. W.	Fair and frosty, if wind N. or N. E. Rain or snow if S. or S. W.
— 8 and 10 "	Ditto.	Ditto.
— 10 and midnight, ...	Fair.	Fair and frosty.

OBSERVATIONS.

1. The nearer the time of the moon's change, first quarter, full and last quarter, are to *midnight*, the fairer will the weather be during the seven days following.

2. The space for this calculation occupies from 10 at night till 2 next morning.

3. The nearer to *midday* or *noon* the phases of the moon happen, the more foul or wet weather may be expected during the next seven days.

4. The space for this calculation occupies from 10 in the forenoon to 2 in the afternoon. These observations refer principally to the summer, though they affect spring and autumn nearly in the same ratio.

5. The moon's change, first quarter, full and last quarter, happening during six of the afternoon hours, i. e. from 4 to 10, may be allowed by fair weather; but this is mostly dependent on the wind, as noted in the table.

6. Though the weather, from a variety of irregular causes, is more uncertain in the latter part of autumn, the whole winter, and the beginning of spring, yet in the main, the above observations will apply to those periods also.

7. To prognosticate correctly, especially in those cases where the wind is concerned, the observer should be within sight of a good vane, where the four cardinal points of the heavens are correctly placed. With this precaution, he will scarcely ever be deceived in depending on the table.—*Dr. Adam Clarke.*

Preserving Roots.

[*From the Yankee Farmer.*]

Every person that has a family should lay in a good stock of roots for winter, whether he raises them or not; if he raise them, the best should be selected in the fall and properly preserved; and if he has to purchase them, then he should do it while they are in good condition, and save them well, instead of buying them after they have lost much of their good qualities, as is the case when they are saved without proper attention.

Beets, carrots, turnips, parsnips, &c. are often put into the cellar without any protection from the air, and they soon become dry and poor, or they may be put in large piles in a warm cellar and heat, and thus become poor. These roots of the proper shape and quality, should be selected very soon after they are dug, and saved in pure earth or sand. If there be a convenient place to lay them on the ground in a bin, or corner of the cellar, in small quantities, they may be saved well by covering them well with earth; if the quantity of roots be large, there should be alternate layers of roots and earth. If it be convenient, it is as well to put the roots in a close box or cask, first a layer of earth, then one of roots, and a good covering of earth on top. Either of these methods may be followed, as most convenient. The roots are best saved by being embedded closely in earth and having enough to cover them to prevent its drying readily.

When roots are covered with earth, they may be saved in a cooler cellar than when exposed, as they will be much less liable to freeze, and when thus protected they keep better where it is tolerably cool. Any pure earth, having only a common degree of moisture, is good for saving roots, and will answer about as well as sand if it be fine so that it will run down closely and cover them. A person living in a city and having only a garden spot, can generally get good earth for this purpose, by removing the top as far as it has been cultivated and taking up the pure soil below.

Most farmers have good cellars in which they can lay their potatoes on the earth, and by keeping their cellars shut close and free from light, they usually save their potatoes well without covering them, but they must not infer from this that other roots may be kept well in the same manner, for as they are more liable to injury from being dried and exposed to air, they should be protected with more care.

We have known good turnips and beets become very poor in a few months, when with proper care in laying them down in earth they might have been kept perfectly good till warm weather. We had some early garden stone turnips last fall, which kind is of as transient duration as any kind cultivated; we put them in a barrel with layers of earth, and they were excellent the first of May; they continued good till the warm weather caused them to grow.

Most persons that raise parsnips let them remain in the ground till spring, and then they can have only a few messes before they begin to grow; instead of this way, a part should be dug and put in the cellar, packed in earth, that they may be used as wanted through the winter.

The best roots for eating are of a small or middling size; the large ones should be given to stock. Turnips that were sown late and have acquired only one third or one half the usual size, are of a much better quality for present use, and they keep far better than those that have a full growth.

There is generally time enough to raise turnips for winter use after digging early potatoes. Some of sufficient size were raised in that way last year, and we have seen some this season that have already attained a good size for eating, on ground that has produced a crop of potatoes; and they will probably grow a month or more yet.

Receipt for Curing Pork and Hams.

[*From the Farmers' Cabinet.*]

As soon as the pork becomes cool, I cut and sort it, taking great care to have the tubs perfectly sweet and clean. In cutting, I take out all the spare ribs, and make pickled pork of all the side between the ham and the shoulders; cutting it into pieces of suitable size for family use. I trim the hams and shoulders well. I cover the bottom of the tub with rock salt, and then put in a layer of pork, nicely packed; then cover this layer with salt, and so on, until the tub is filled. I use rock salt and very bountifully. In six or eight days, make a pickle of salt, and cold water, as strong as possible, and cover the pork previously salted with it. It will then keep for use for years if you choose.

In preparing the hams and shoulders, I weigh several, to come at the probable weight of the whole. They are packed with great care, in suitable tubs. My process is to sprinkle some coarse salt at the bottom; then pack in the hams and shoulders firmly, side by side, being careful not to put the back of one flat on the top of another. The spaces are filled up with chines, hocks and jowls. To about every 300 weight of meat, I take 30 pounds of rock salt, one pound of salt petre, and fourteen pounds of brown sugar, or half a gallon of good molasses, (generally the latter.) Take as much pure water as will cover the meat, put in a clean vessel, add the above articles, boil it, removing the scum as it rises, and when no more rises set it to cool, after which pour it on the meat until it is covered three or four inches.

If the hams are small, weighing from 12 to 15 pounds, let them remain in the pickle five weeks—if from 15 to 25, six weeks—if from 25 to 45 seven weeks. When you remove them for the purpose of smoking, put them in clean cold water for two or three hours. If there is too much salt or salt petre adhering to the surface of the hams, the water will take it off. The smoke should be made of clean green hickory. A fire should be built only in dry weather. And when the meat has acquired a yellow tinge, not red or black, they are removed and hung up in a dark place where they are not disturbed by flies or vermin. DAVID COMFORT.

Things a Farmer should not do.

[*From the Common School Assistant.*]

1. A farmer should never undertake to cultivate more land than he can do thoroughly; half-tilled land is growing poorer; well tilled land is constantly improving.

2. A farmer should never keep more cattle, horses, sheep or hogs, than he can keep in good order: an animal in high order the first of December, is already half wintered.

3. A farmer should never depend on his neighbor, for what he can by care and good management produce on his own farm; he should never beg fruit while he can plant trees, or borrow tools when he can make or buy; a high authority has said, the borrower is a servant to the lender.

4. The farmer should never be so immersed in political matters as to forget to sow his wheat, dig his potatoes and bank up his cellar; nor should he be so inattentive to them as to be ignorant of those great questions of national and state policy which will always agitate, more or less, a free people.

5. A farmer should shun the doors of a bank as he would the approach of the plague or cholera; banks are for traders and men of speculation, and theirs is a business with which farmers have little to do.

6. A farmer should never be ashamed of his calling; we know that no man can be entirely independent, yet the farmer should remember, that if any one is said to possess that enviable distinction, he is the man.

7. No farmer should allow the reproach of neglecting education to lie against himself or family: if knowledge is power, the beginning of it should be early and deeply laid in the district school.

8. A farmer should never use ardent spirits as a drink; if, while undergoing severe fatigue and the hard labor of the summer he would enjoy robust health, let him be temperate in all things.

9. A farmer never should refuse a fair price for any thing he wants to sell; we have known a man who had several hundred bushels of wheat to dispose of, refuse 8s. because he wanted 8s. 6d. and after keeping his wheat six months, was glad to get 6s. 6s. for it.

10. A farmer should never allow his wood house to be emptied of wood during the summer season; if he does, when winter comes, in addition to cold fingers, he must expect to encounter the chilling looks of his wife, and perhaps be compelled, in a series of lectures, to learn that the man who burns green wood has not mastered the A B C of domestic economy.

11. A farmer should never allow a window to be filled with red cloaks, tattered coats, and old hats; if he does he will most assuredly acquire the reputation of a man who tarries long at the whiskey, leaving his wife and children to starve at home.

Facts for the Fireside.

[*From the Vermont Phœnix.*]

'Tis thus Benevolence her laws fulfils,
And Justice executes what Nature wills.

All the laws of Nature, but especially those of our own organization, are instituted in infinite benevolence; and every instance of pain, sickness and suffering, is an example of the penalty attached to one or more of these violated laws.

The two most prominent laws of our organization relate to nutriment and exercise.

Our bodies are made up of organs fitted to the performance of certain functions. These organs, thus in a state of constant *action* necessarily occasion a wear and waste; and this waste demands a supply for the usual reparation. Whence then is this supply derived?—Chiefly from solids and fluids received into the stomach. Under the influence of the vital power the necessary selection and appropriation is made.

A diet too poor and unstimulating often begets scrofula and many other constitutional maladies. The poor Irish, and the hungry herds who subsist on the meagre pittance of soup societies, are painful examples of the truth of this remark. Among the opulent, however, the opposite error prevails—as their bloated forms and gouty limbs plainly show.

Gluttony is a breach of the law, the penalty of which is so irretrievable that no violator can escape.

A certain amount of food is necessary for the healthy support of the human body, and every iota taken into the stomach, over and above what the law of nature requires, tends to weaken the constitution and induce disease.

The quantity that some people are able to crowd into their stomachs, by long habits of gluttony, is indeed enormous. A case is recorded of a man who ate 64 pounds of food daily, for six days; and another of a Frenchman who used to eat his own weight of beef every 24 hours. A man, recently, in the state of Maine was at work felling trees, and had his dinner brought him at 12 o'clock. At 2 o'clock he left his work, saying he should work no longer unless he could get something more to eat. On inquiry, it was found that he had eaten for his dinner the following articles, viz:—two quarts of fish and potatoes, two quarts of bread and milk, two quarts of old cider, and a one quart or a three quart dish of baked pudding—the good lady of the house did not recollect which. The gentleman who employed him very wisely remarked, that he did not hire him oftener than he could help, for he thought it must take nearly all his strength to digest his food.

It is a fact that the great mass of the community eat food not only too rich and stimulating in quality, but also use far too much in quantity. And but a glance at the community will show that their penalties are meted out in the form of dyspepsias, liver diseases, dropsy, gout, and premature death.

The tender mother wonders that her sinless offspring should suffer so much pain, and then be snatched from her tender embrace by a "mysterious providence," when in fact the child only suffers the penalty of just and immutable laws which her own pampering has broken.

The stomach, like every other organ, requires rest after the performance of its labor. And yet how every mother will tell her dyspeptic son to "eat little and often." Oh, ruinous practice! "eat little and often"—the echo of these words has been the death dirge of thousands. Ah! how does it ring upon the ear of the poor dyspeptic, and how does it hasten his progress to that grave which he so much dreads!

The Wealth of a Country depends upon the Farmers and Mechanics.

[*From the Maine Farmer.*]

What is wealth? Those things which are convenient and necessary to use, and which administer to our wants and our comforts. Money alone, cannot therefore, be considered as wealth, because if the articles or things above mentioned are not to be had, or are not in existence, a man would be poor indeed, though he were loaded with gold and silver. If he were hungry and there was no bread to be bought, if he were shivering with cold and there were no garments made for sale, his gold would be but of little service. It is true, mankind, by a common consent, have agreed that gold and silver should be the sign or evidence of property,—or in other words, the *measure* of property; and he who has a certain amount of it, has evidence of so much wealth.—He can exchange it for the very things or articles which do in fact constitute wealth.

Thus a man who has a hundred dollars in his pocket has the *ticket*, as it were, to entitle him to *enter* into the possession of an hundred bushels of corn, or a hundred yards of cloth, or a hundred acres of wild land,—or a yoke of oxen, or a horse and wagon, as the case may be. But if these things do not exist, and he needs them, his *ticket* is of no more use, than if he had a ticket to go into a theatre, and it should have been burned down before he used it. The elements therefore of wealth consists in natural productions, brought together, changed and modified by the skill and labor of man; of the farmer and mechanic. Commerce, though necessary and honorable, is nothing more than the *moving* or *changing* of these productions from place to place. It has always appeared singular to us, that merchants should consider themselves, as too many, far too many of them do, above the farmers or the mechanics, merely on account of their profession, when they are indeed only the *teamsters*, to the others. They are the agents to transport their productions hither and thither, as calls may exist for them. But to return to the subject. If we are right in the position which we have taken, that wealth consists in natural productions changed and wrought upon by the labor of man, it follows that the country which possesses the most of the elements or materials to work upon, such as good soil—abundance of water power—forest of timber—quarries of different kinds of stones, mines, and beds of different kinds of minerals, &c. &c., must have the most natural wealth. It then only requires the hand of industry and skill to put these materials into shape, and to put them together to form real substantial wealth. This is the duty of the farmer and mechanic. They are the second creators of wealth.—They take the raw materials as it came from the hands of the Almighty, and change it by their labor into the thousands and tens of thousands of different forms which render it useful to man, which make it subservient to the wants and comforts of human life. The more industrious and skilful this class is, the more wealth will be accumulated in the country. Do farmers and mechanics consider these things rightly? Are they not too apt to think themselves as mere plodders and servants, rather than as second to the great first cause in the production and increase of wealth? And indeed is there not a false standard of respectability too much in use in society, and are not the productive classes apt to measure themselves by it? This standard appears to be *idleness and a fine coat;* and consequently, the more idle a man can be, and the finer the dress, the more of a gentleman. Not so. Respectability should consist in an improved mind, and skilful and industrious hands.—Moral qualifications being equal, he should have the most honor, who, by the combination of the efforts of his mind and physical powers, has contributed most largely to the increase of those things which constitute wealth.

Such an one has done more for the amelioration of society, than a thousand unproductive *dandies*, who loll in the shade and wash in Cologne. And society should bestow upon such a corresponding meed of honor.

New Mode of Stacking Grain.

[*From the Farmers' Magazine.*]

Sir,—The long continuance of rain in this part of the country has occasioned many very serious losses in our hay crops, and as the weather continues here in a very unsettled state, I am apprehensive hill farmers may probably suffer considerably in the ensuing corn harvest, unless every precaution is taken which prudence may dictate. I am therfore induced to intrude on you for a small space in your valuable publication, to state a practice which farmers in the upper part of the county of Cardigan are in the habit of, and without which I am convinced they would in the generality of seasons lose a very large portion of their corn. Our hills are much more subject to rain than the land in England, I therefore do not presume to offer advice to any but those who are situate as we are. Our practice in the upper part of Cardiganshire is to bind *all* our corn, spring as well as winter crops, and to put them into small mows in the field in the shape of a sugar-loaf. We begin each mow by placing three sheaves on the stubble, the head of each sheaf inclining to the centre of the intended mow, and resting on the binding of the sheaf next to it. We then build our mow by adding other sheaves, the heads of which resting on the three laid as a foundation, gives a position to the but of each succeeding sheaf, inclining downward so as to throw off the rain. In this manner we proceed until we have added as many sheaves as will nearly make a load for the vehicle we have (whether cart or wagon) to carry with. We then contract the top of the mow to as sharp a point as possible, over which we place a reversed sheaf banded close to the but, and with a long rod running down through it into the top of the mow, spreading the ears of the upper sheaf or cap as equally round the mow as we can. By this method I have had corn which has stood in the field three weeks during continued rain brough home without the loss of a single sheaf. I am not sure but the above practice may be generally *known* to hill farmers in different parts of the kingdom, but I am quite sure it is not generally practised by them, as I have very frequently seen beautiful crops of corn within a few miles of me, spoiled by farmers attempting to harvest them in the manner of the English farmers. I am, sir, your very humble servant. A. C. F.

18th July, 1838

There is one material advantage in the above practice which should be noticed. We can get up our crop into mow between showers, and carry home in similar opportunities, without exposing more than one load at a time to the weather.

What has become of Mr. Kimberley's plan, noticed in your magazine for February last, page 89? I am fully persuaded it is practicable, and am anxiously looking for the development.

Horticultural Exhibition.

The large room in the Stuyvesant Institute, has been graced the last three days with very a choice variety of fruits and vegetables, sent by contributors to the exhibition of the Horticultural Society of the country on the Hudson. This association has only been formed the present season, and this is the first attempt to array the products of the society before the public. The society being yet in its infancy, the exhibition does not, of course, embrace the extent and variety of articles that might be expected of older and more mature associations, but what has been gathered is of rare quality and fine appearance.

The garden and nurseries of the Downings, at Newburg, have contributed fruits of the finest flavor and size. The grapes and plumbs, gages, pears, apples and peaches from that place are a beautiful sight, and display a taste and culture highly creditable to the cultivators. Not less praiseworthy are those of Roe, of Newburgh. The black Hamburgh grapes of both these gardens, as well as those of J. P. Cushing, at Watertown, near Boston, appear to be fine beyond example. The other varieties of this fruit are numerous. A kind of pear called Dutchess D'Angoulcime, produced by E. Vose, of Dorchester, Mass. is very fine in appearance, as well as some fruit* from the farm of Judge Buel, of Albany. The sickel pears of Mr. Arden, of West Point, are a superior fruit, excelling, undoubtedly, the vergalu, which is falling into neglect. The black Hamburgh grapes of Miss Verplanck, Fishkill Landing, raised in the open air, are, we think, equal to those of Cushing, under glass. The Muscat of Lunel, however, of the last mentioned person, presents tempting clusters.

In the vegetable line, there are numerous parcels, consisting of celery, carrots, parsnips, beets, pumpkins, corn, &c. &c. all of course, mammoth productions, and raised by the best gardeners in our vicinity.

Thorburn seems to have monopolized most of the Dahlias, of which there are hundreds of every hue, and some very rare.

On the whole, the society has made a good beginning, and we hope will thrive in its efforts to increase the taste for horticultural pursuits. The valley of the Hudson is a field which may be yet cultivated with a certainty of its producing fruits which will rival those of the most favored climates.—*Evening Post.*

Rohan Potatoes.—In our last number, we recorded the fact, that friend Orsment, of the United Society, had raised one bushel of potatoes from a single tuber. We have now to notice, that the Hon. William Clark, Jr. of Northampton, raised *two bushels and one peck*, from one Rohan potato.—*Yankee Farmer.*

Durham Cattle.—The Lexington Intelligencer of the 14th September says, there have been two sales of short horn Durham cattle in that neighborhood, being the stock of Maslin and Samuel Smith, Esqrs. At the sale of the latter, a cow and sucking calf sold for $2,100.—Another at $1,350—others at $1,100, $1,000, &c. The whole stock of Samuel Smith sold for between $20,000 and $30,000.

A bold child, who looks you in the face, speaks the truth, and shames the devil—that is the stuff of which to make men good and brave—aye, and wise men.—*Bulwer.*

Expenditures of the Government.

In the House of Representatives, on Thursday last, the Speaker laid before the House a letter from the Secretary of the Treasury, in answer to a resolution of the 25th June, showing the amounts of expenditure, exclusive of the public debt, for each year, from 1824 to 1838. They are as follows, viz:

For the year	1824,	$15,330,444	71
Do	1825,	11,490,459	94
Do	1826,	13,062,316	27
Do	1827,	12,653,095	65
Do	1828,	13,296,041	45
Do	1829,	12,660,460	62
Do	1830,	13,229,553	33
Do	1831,	13,864,067	90
Do	1832,	16,516,388	77
Do	1833,	22,713,755	11
Do	1834,	18,425,417	25
Do	1835,	17,514,950	28
Do	1836,	30,868,164	04
Do	1837,	39,164,745	37*

* This sum is subject to small variation on the settlement of the accounts of the Treasurer.

Note—The above sums include payments for Trust Funds and Indemnities, which, in 1837, were $5,610,404. 36.—*National Intelligencer of July.*

Sickness in the West.—The Land Sales.—The citizens of Northern Indiana have addressed a petition to the President of the United States, asking a postponement of the sales of the public lands in that section. They give as their reasons for making this request, that "there is now prevailing throughout all that section an unparalleled epidemic, that is carrying hundreds to their graves, and thousands to their sick beds, while their crops are rotting in the fields unharvested; amid such universal distress that it renders it impossible for the settlers to make the necessary exertions to obtain the means of purchasing their humble homes."

Young Men's Department.

Poor Richard's Almanac.

*The Way to Wealth, as clearly shown in the Preface of an old Pennsylvania Almanac, entitled, Poor Richard Improved.**

Courteous Reader,—I have heard, that nothing gives an author so great pleasure, as to find his works respectfully quoted by others. Judge, then, how much I must have been gratified by an incident I am going to relate to you. I stopped my horse lately, where a great number of people were collected, at an auction of merchants goods. The hour of the sale not being come, they were conversing on the badness of the times; and one of the company called to a plain clean old man, with white locks, 'Pray, Father Abraham, what think you of the times? Will not these heavy taxes quite ruin the country? How shall we ever be able to pay them? What would you advise us to?'—Father Abraham stood up, and replied, 'If you would have my advice, I will give it to you in short, "for a word to the wise is enough," as Poor Richard says.' They joined in desiring him to speak his mind, and gathering round him, he proceeded as follows:

'Friends,' says he, 'the taxes are, indeed, very heavy and, if those laid on by the government were the only ones we had to pay, we might more easily discharge them; but we have many others, and much more grievous to some of us. We are taxed twice as much by our idleness, three times as much by our pride, and four times as much by our folly; and from these taxes the commissioners cannot ease or deliver us, by allowing an abatement. However, let us hearken to good advice, and something may be done for us; "God helps them that help themselves," as poor Richard says.

'I. It would be thought a hard government that should tax its people one tenth part of their time, to be employed in its service: but idleness taxes many of us much more; sloth, by bringing on diseases, absolutely shortens life. "Sloth, like rust, consumes faster than labor wears, while the used key is always bright," as poor Richard says. "But dost thou love life, then do not squander time, for that is the stuff life is made of," as poor Richard says. How much more than is necessary do we spend in sleep! forgetting, that "the sleeping fox catches no poultry, and that there will be sleeping enough in the grave," as poor Richard says.

'"If time be of all things the most precious, wasting time must be," as poor Richard says, "the greatest prodigality;" since, as he elsewhere tells us, "lost time is never found again; and what we call time enough always proves little enough;" let us then up and be doing, and doing to the purpose; so by diligence shall we do more with less perplexity. "Sloth makes all things difficult, but industry all easy; and he that riseth late, must trot all day, and shall scarce overtake his business at night; while laziness travels so slowly, that poverty soon overtakes him. Drive thy business, let not that drive thee; and early to bed, early to rise, makes a man healthy, wealthy, and wise," as poor Richard says.

---

* This "*some fruit*" comprised samples of 36 varieties of autumn and winter apples, of known celebrity, and about 20 varieties of pears.—*Cond.*

* Dr. Franklin for many years published the Pennsylvania Almanac, called *Poor Richard* [*Saunders*,] and furnished i with various sentences and proverbs, which had principal relation to the topics of "industry, attention to one's own business, and frugality." The whole or chief of these sentence and proverbs he at last collected and digested in the above general preface, which were read with much avidity and profi and perhaps tended more to the formation of a national ch racter in America, than any other cause.

'So what signifies wishing and hoping for better times? We may make these times better, if we bestir ourselves. "Industry need not wish, and he that lives upon hope will die fasting. There are no gains without pains; then help hands, for I have no lands," or, if I have, they are smartly taxed. "He, that hath a trade, hath an estate; and, he that hath a calling, hath an office of profit and honor," as poor Richard says; but then the trade must be worked at, and the calling well followed, or neither the estate nor the office will enable to us pay our taxes. If we are industrious, we shall never starve; for, "at the working man's house, hunger looks in, but dares not enter." Nor will the bailiff or the constable enter, for "industry pays debts, while despair increaseth them." What though you have found no treasure, nor has any rich relation left you a legacy, "diligence is the mother of good luck, and God gives all things to industry. Then plough deep, while sluggards sleep, and you shall have corn to sell and to keep."—Work while it is called to-day, for you know not how much you may be hindered to-morrow. "One to-day is worth two to-morrows," as poor Richard says; and farther, "never leave that till to-morrow, which you can do to-day." If you were a servant, would you not be ashamed that a good master should catch you idle? Are you then your own master? Be ashamed to catch yourself idle, when there is so much to be done for yourself, your family, your country, and your king. Handle your tools without mittens; remember, that "the cat in gloves catches no mice," as poor Richard says. It is true, there is much to be done, and perhaps you are weak-handed; but stick to it steadily, and you will see great effects, for "constant dropping wears away stones; and by diligence and patience the mouse ate in two the cable; and little strokes fell great oaks."

'Methinks I hear some of you say, "must a man afford himself no leisure?" I will tell thee, my friend, what poor Richard says; "employ thy time well, if thou meanest to gain leisure; and since thou are not sure of a minute, throw not away an hour." Leisure is time for doing some thing useful; this leisure the diligent man will obtain, but the lazy man never; for "a life of leisure and a life of laziness are two things.—Many, without labor, would live by their wits only, but they break for want of stock;" whereas industry gives comfort, and plenty, and respect. "Fly pleasures, and they will follow you. The diligent spinner has a large shift; and now I have a sheep and a cow, every one bids me good-morrow."

'II. But with our industry we must likewise be steady, settled, and careful, and oversee our own affairs with our own eyes, and not trust too much to others; for, as poor Richard says,

> "I never saw an oft removed tree,
> Nor yet an oft-removed family,
> That throve so well as those that settled be."

And again, "three removes is as bad as a fire;" and again, "keep thy shop, and thy shop will keep thee;" and again, "if you would have your business done, go, if not, send." And again,

> "He that by the plough would thrive,
> Himself must either hold or drive."

And again, "the eye of a master will do more work than both his hands;" and again, "want of care does us more damage than want of knowledge and;" again, "not to oversee workmen, is to leave them your purse open." Trusting too much to other's care is the ruin of many; for, "in the affairs of this world, men are saved, not by faith, but by the want of it;" but a man's own care is profitable; for, "if you would have a faithful servant, and one that you like, serve yourself. A little neglect may breed great mischief; for want of a nail the shoe was lost, and for want of a shoe the horse was lost, and for want of a horse the rider was lost," being overtaken and slain by the enemy; all for want of a little care about a horse-shoe nail.

'III. So much for industry, my friends, and attention to one's own business; but to these we must add frugality, if we would make our industry more certainly successful. A man may, if he knows not how to save as he gets, "keep his nose all his life to the grindstone, and die not worth a groat at last. A fat kitchen makes a lean will;" and

> "Many estates are spent in the getting,
> Since women for tea forsook spinning and knitting,
> And men for punch forsook hewing and splitting."

"If you would be wealthy, think of saving, as well as of getting. The Indies have not made Spain rich, because her outgoes are greater than her incomes."

'Away then, with your expensive follies, and you will not then have so much cause to complain of hard times, heavy taxes, and chargable families; for,

> "Women and wine, game and deceit,
> Make the wealth small, and the want great."

And farther, "what maintains one vice, would bring up two children." You may think, perhaps, that a little tea, or a little punch now and then, diet a little more costly, clothes a little finer, and a little entertainment now and then, can be no great matter; but remember, "many a little makes a mickle." Beware of little expenses; "a small leak will sink a great ship," as poor Richard says; and again, "who dainties love, shall beggars prove;" and moreover, "fools make feasts, and wise men eat them."

'Here you are all got together to this sale of fineries and nick-nacks. You call them *goods*, but if you do not take care, they will prove *evils* to some of you. You expect they will be sold cheap, and perhaps they may, for less than they cost; but, if you have no occasion for them, they must be dear to you. Remember what poor Richard says, "buy what thou hast no need of, and ere long thou shalt sell thy necessaries." And again, "at a great penny-worth pause a while." He means, that perhaps the cheapness is apparent only, and not real; or the bargain, by straitening thee in thy business, may do thee more harm than good. For in another place he says, "many have been ruined by buying good penny-worths." Again, "it is foolish to lay out money in a purchase of repentance;" and yet this folly is practised every day at auctions, for want of minding the almanac. Many a one, for the sake of finery on the back, have gone with a hungry belly, and half starved their families; "silks and satins, scarlet and velvets, put out the kitchen fire," as poor Richard says. These are not the necessaries of life, they can scarcely be called the conveniencies; and yet, only because they look pretty, how many want to have them? By these and other extravagancies, the genteel are reduced to poverty, and forced to borrow of those whom they formerly despised, but who, through industry and frugality, have maintained their standing; in which case it appears plainly, that "a ploughman on his legs is higher than a gentleman on his knees," as poor Richard says. Perhaps they have had a small estate left them, which they knew not the getting of; they think "it is day, and it will never be night; that a little to be spent out of so much is not worth minding; but always taking out of the meal-tub, and never putting in soon comes to the bottom," as poor Richard says; and then, "when the well is dry, they know the worth of water." But this they might have known before, if they had taken his advice; "if you would know the value of money go and try to borrow some; for he that goes a borrowing goes a sorrowing," as poor Richard says; and indeed so does he that lends to such people, when he goes to get it again. Poor Dick farther advises, and says,

> "Fond pride of dress, is sure a curse,
> Ere fancy you consult, consult your purse."

And again, "pride is as loud a beggar as want, and a great deal more saucy." When you have bought one fine thing, you must buy ten more, that your appearance may be all of a piece; but poor Dick says, "it is easier to suppress the first desire than to satisfy all that follow it;" and it is as truly folly for the poor to ape the rich, as for the frog to swell in order to equal the ox.

> "Vessels large may venture more,
> But little boats should keep near shore."

It is, however, a folly soon punished; for, as poor Richard says, "pride that dines on vanity, sups on contempt; pride breakfasted with plenty, dined with poverty, and supped with infamy." And, after all, of what use is this pride of appearance, for which so much is risked, so much is suffered? It cannot promote health, nor ease pain; it makes no increase of merit in the person; it creates envy, it hastens misfortune.

'But what madness must it be to *run in debt* for these superfluities! We are offered by the terms of this sale six months credit; and that perhaps has induced some of us to attend it, because we cannot spare the ready money, and hope now to be fine without it. But ah! think what you do when you run in debt; you give to another power over your liberty. If you cannot pay at the time, you will be ashamed to see your creditor, you will be in fear when you speak to him, when you will make poor pitiful sneaking excuses, and by degrees come to lose your veracity, and sink into base, downright lying; for, "the second vice is lying; the *first* is running in debt," as poor Richard says; and again to the same purpose, "lying rides upon debt's back;" whereas a free-born Englishman ought not to be ashamed nor afraid to see or speak to any man living. But poverty often deprives a man of all spirit and virtue. "It is hard for an empty bag to stand upright." What would you think of that prince, or of that government, who should issue an edict forbidding you to dress like a gentleman or gentlewoman, on pain of imprisonment or servitude? Would you not say, that you were free, have a right to dress as you please, and that such an edict would be a breach of your privileges, and such a government tyrannical? And yet you are about to put yourself under that tyranny, when you run in debt for such dress! your creditor has authority, at his pleasure, to deprive you of your liberty, by confining you in a gaol for life, or by selling you for a servant, if you should not be able to pay him. When you have got your bargain, you may, perhaps, think little of payment; but, as poor Richard says, "creditors have better memories than debtors; creditors are a superstitious sect, great observers of set-days and times." The day comes round before you are aware, and the demand is made before you are prepared to satisfy it; or, if you bear your debt in mind, the term, which at first seemed so long, will as it lessens, appear extremely short; time will seem to have added wings to his heels as well as his shoulders.—"Those have a short lent, who owe money to be paid at Easter." At present, perhaps, you may think yourselves in thriving circumstances, and that you can bear a little extravagance without injury; but

> "For age and want save while you may,
> No morning sun lasts a whole day."

Gain may be temporary and uncertain, but ever, while you live, expense is constant and certain; and, "it is easier to build two chimneys than to keep one in fuel," as poor Richard says; so, "rather go to bed supperless than rise in debt."

> "Get what you can, and what you get hold,
> 'Tis the stone that will turn all your lead into gold."

And when you have got the philosopher's stone, sure you will no longer complain of bad times, or the difficulty of paying taxes.

'IV. This doctrine, my friends, is reason and wisdom; but, after all, do not depend too much upon your own industry, and frugality, and prudence, though excellent things; for they may all be blasted, without the blessing of heaven; and therefore ask that blessing humbly, and be not uncharitable to those that at present seem to want it, but comfort and help them. Remember Job suffered, and was afterwards prosperous.

'And now, to conclude, "experience keeps a dear school, but fools will learn in no other," as poor Richard says, and scarce in that; for, it is true, "we may give advice, but we cannot give conduct:" however, remember this, "they that will not be counselled cannot be helped;" and father, that "if you will not hear reason she will surely rap your knuckles," as poor Richard says.'

Thus the old gentleman ended his harangue. The people heard it, and approved the doctrine; and immediately practised the contrary, just as if it had been a common sermon, for the auction opened and they began to buy extravagantly.—I found the good man had thoroughly studied my almanacs, and digested all I had dropt on those topics during the course of twenty-five years. The frequent mention he made of me must have tired any one else: but my vanity was wonderfully delighted with it, though I was conscious, that not a tenth part of the wisdom was my own, which he ascribed to me, but rather the gleanings that I had made of the sense of all ages and nations. However, I resolved to be the better for the echo of it; and, though I had at first determined to buy stuff for a new coat, I went away, resolved to wear my old one a little longer. Reader, if thou will do the same, thy profit will be as great as mine.

I am as ever, thine to serve thee,
RICHARD SAUNDERS.

Chemical Catechism—Chapter VI.

[*From Parkes's Chemical Catechism.*]

OF LIME.

How is lime to be distinguished from the other earths?

Lime is of a white colour, and of a hot caustic taste; it forms peculiar salts with acids, which is perhaps the most decisive proof that can ever be obtained to identify this or any other earth: it changes vegetable blues to a green; it is incapable of fusion; it solidifies water,* when sprinkled with that fluid, occasioning it to give out a greater quantity of caloric; it absorbs moisture and carbonic acid,† when exposed to atmospheric air; but is itself very sparingly soluble in water, and possesses the peculiar property of dissolving more copiously in cold than in hot water.

In what state is lime found in nature?

Lime is never found pure; it is always in a state of combination, generally with an acid, and more frequently with the carbonic acid, as in chalk, marble, limestone, &c.‡ It is found also in vegetables, and is the basis of animal bones. It occurs likewise in the waters of all springs and rivers.

---

* Quick-lime has such an affinity for water that it will absorb one-fourth of its weight of that fluid, and yet remain perfectly dry. The water becomes solidified and identified with the earth. The heat, therefore, that is evolved in the process of slaking lime, proceeds from the water as it passes to the solid state, and not from the earth as is sometimes supposed.

† The effect of carbonic acid upon lime may be shown by the following experiment:—Add gradually a very small quantity of water impregnated with carbonic acid, to a jar about one-fourth filled with lime-water. A milkiness will ensue, because the carbonic acid forms with the lime an insoluble compound. On adding more of the carbonated water, and shaking the jar as these additions are made, the milkiness at last disappears, and the whole precipitates becomes re-dissolved. Hence, it appears that lime with a *small* quantity of carbonic acid is insoluble, and soluble with a *larger* quantity.

‡ The vast mountains of calcareous earth which occur in different parts of the world, owe their origin, in general, it is supposed, to the destruction of marine testacious animals, which in long process of time, formed these extensive and accumulated heaps.

> "For in vast shoals beneath the brineless tide,
> On earth's firm crust, testaceous tribes reside:
> Age after age expands the peopled plain,
> The tenants perish, but their cells remain:
> Whence coral walls and sparry hills ascend
> From pole to pole, and round the line extend."—*Darwin.*

Fourcroy, in his *Chemical Elements*, has given a beautiful account of this process of nature, to which I refer; as I am persuaded every reader of taste must be charmed with its perusal. See *Dr. John Thompson's Edition, part iii. chap. 7, sect.* 1.

According to Capt. Cook, there are in the Southern Ocean, perpendicular coralline rocks, formed entirely of sea-shells, which are of such magnitude as to render the navigation of those seas extremely dangerous.

The shells of some testaceous animals in the South Sea are of a vast size. The *kemo* shell on the coast of Sumatra is frequently found three or four feet in diameter, and as white as ivory. See *Marsden's History of the Island of Sumatra, page* 10.

It may he remarked, that while *testaceous* shells are formed with carbonate of lime, the shells of *crustaceous* animals, and the shells of birds' eggs contain also a portion of phosphate of lime. Its use in the former is not known; but the design of nature in furnishing the shells of eggs with phosphoric acid is very apparent. The body of the egg contains neither phosphoric acid or lime: it was necessary, therefore, that nature should provide means of furnishing both these substances, which it does at the expense of the shell; which becomes thinner and thinner during the whole time of incubation, till the living embryo hath appropriated a sufficient quantity for

How is lime procured from these minerals?

Carbonate of lime, by whatever name it is called, whether chalk, marble, limestone, oyster shell, &c. is broken into convenient pieces, and piled in alternate layers, with coal, furze or other fuel, in proper kilns, where it is kept for a considerable time in a *white* heat. By this means, the carbonic acid and water are driven off, and tolerably pure lime is the product.*

What are the chief uses of lime?

Lime united with the acids is applied to various useful purposes, and next to silica, forms a material portion of the solid fabric of the terrestrial globe. In its pure state, it is used in many of the arts,† particularly in making mortar for buildings. It is employed by the farmers as a manure; also by bleachers, tanners, sugar bakers, soap-boilers, iron masters,‡ and others, in their several manufactories, and in medicine.

How do you explain the operation of lime in forming mortar?

Pure lime has, when united to a certain portion of water, a very strong affinity for silica, another most essential ingredient in all mortar and cements; for without this it never hardens—but when mixed in proper proportions, the gradual absorption of carbonic acid from the atmosphere occasions it in a series of years to become as hard as unburnt limestone.§

How does lime act so as to be of use as a manure for land?

The use of lime in agriculture may be attributed to the property which it possesses of hastening the dissolution and putrefaction of all animal and vegetable matter,|| and of imparting to the soil a power of retaining a quantity of moisture necessary for the nourishment and vigorous growth of the plants, corn, &c.¶ for there is no good soil that does not contain a certain portion of lime, though always, without exception, combined with carbonic acid.

What is the use of lime in the operation of tanning leather?

Lime is used by the tanner in a state of solution; in this the hides are immersed in order to dissolve the gelatinous part of the skin, and to facilitate the removal of the hair.**

How is lime used in refining sugar?

By boiling the sugar in lime-water the manufacturer deprives it of a certain uncombined acid,* which prevents its crystallization.

What is the use of lime in the manufacture of soap?

Lime is mixed with the alkali in order to deprive it of carbonic acid. The alkali is thus rendered what is called *caustic*, and by this means is fitted to combine with the oil or tallow which is thereby converted into soap.

We have hitherto spoken only of lime and of carbonate of lime:—Is lime found in any other state of combination?

Yes: lime occurs in combination with sulphuric acid forming gypsum;† with the fluoric acid constituting fluor spar;‡ with the phosphoric acid in a mineral called *apatite*,§ and in some precious stones.

What is magnesia?

Magnesia is a very soft, white light earth, with little taste or smell; unalterable in the fire, and almost insoluble in water. Nevertheless it absorbs a considerable portion of water when that fluid is poured upon it, and heat is evolved. It dissolves in alkaline carbonates, but is not soluble in the caustic alkalies.

How is magnesia procured?

Magnesia is never found in a state of purity, but always in combination with some acid. It is generally procured from sulphate of magnesia,|| which exists with the muriate of this earth in sea-water, and in many springs. Magnesia is also a component part of several minerals.

What are the uses of magnesia?

Pure magnesia, as well as the sulphate and carbonate, has important uses in medicine.¶ It is also required in some chemical processes, and is employed by the manufacturers of enamels and procelain. Calcined magnesia is also the most effectual antidote in case of poison by the mineral acids.

We have spoken of each of the earths separately, but are there not instances in nature of the earths entering into combination with each other?

Yes: minerals are found in every part of the world, in which the earths are combined in different proportions by processes unknown to us, which nature employs to produce that endless variety of what, in common language, we call rocks, stones, gems,** &c.

Is the design of Nature in forming so many distinct earths very apparent?

The earths have several properties in common; yet as every earth possesses different and specific properties, it is evident that Nature designed them for different and distinct purposes of utility.

You have enumerated the separate uses of most of the earths:—Can you recollect the collective advantages which arise from this class of bodies?

The uses of some of these earths are not yet discovered; but the benefits which we derive from lime, clay, silica, and magnesia, are very various and important.

In order to impress your memory, and to finish the consideration of this class of bodies, endeavour to recollect some of the more important uses of those earths with which you are best acquainted.

Lime, then, has an extensive and important use in agriculture;†† it is employed in building, &c. and adds much both to the neatness and durability of our dwellings. Silica is the basis of all mortar and cements, and is a necessary ingredient in earthen-ware, porcelain, and glass. Barytes is employed in chemical laboratories as a re-agent. Magnesia, besides being the basis of several salts, is of great use in medicine; and Alumina, by a due mixture with silica, is capable of forming vessels for chemists that will resist the action of the most concentrated acids; it is the material of which the bricks are formed which construct the walls of our habitations, and it is also spread out by the great Author of nature in strata within our hills and mountains, to arrest the progress of subterraneous waters, and to produce those springs that fertilize the valleys, and which take such diversified courses upon the surface of the globe.

---

the formation of its bones. Part of the albumen combines with the shell for this purpose, and another portion forms feathers.

One thousand parts of egg shells are composed of

Carbonate of lime, ...	896
Phosphate of lime,..............	57
Gluten and moisture, ...	47
	1000

If fowls are kept in a state of confinement, where they cannot get at any calcareous earth, they lay their eggs without shells.

* Bishop Watson found by experiment, that upon an average, every ton of limestone produced 11 cwt. 1 qr. 4 lbs. of quick-lime, weighed before it was cold; and that when exposed to the air it increased in weight daily, at the rate of a hundred weight per ton for the first five or six days after it was drawn from the kiln. This fact is worth the notice of those farmers who fetch their lime from great distances.

† Lime is used in the manufacture of glue. The design of it is to prevent its becoming flexible by the absorption of moisture, and to add to its strength. Some persons use alum for the same purposes.

‡ The iron ores that are wrought in this country, contain a large portion of alumina, and silica: in order, therefore, to flux these earths, and more effectually separate the iron, a quantity of lime is usually mixed with the ore in the furnace; lime having the property of rendering the other earths more fusible.

§ When lime is made into mortar, it takes a long time in acquiring the portion of carbonic acid which it possessed in the quarry; but the mortar hardens as this absorption takes place. This accounts for the great strength of some ancient buildings, in which the mortar is found to have a greater degree of firmness than even limestone itself.

The nature of the sand which is mixed with lime to form mortar or cement, is of the utmost consequence; the harder and sharper the sand, the better, for if this matter be of a friable nature like chalk, the mortar must be weak.

|| When quick-lime is spread upon arable land, it destroys by its causticity the organization of all animal and vegetable matters remaining in the soil, and thus renders them a fit pabulum for the future crop. In like manner the lime would also burn up the tender shoots of the fresh plants, and sterilize instead of fructifying the ground; but Nature has so ordered it, that, as the lime falls to powder upon the land it should gradually absorb carbonic acid from the atmosphere, which deprives it of its causticity and converts it into chalk.

¶ Hence lime and chalk are found to be particularly useful on sandy soils. Marl is a mixture of carbonate of lime and clay. See additional notes, No. 20. Marls are useful in agriculture only in proportion to the calcareous earth they contain. Unless they contain more than 30 per cent of lime, they are of no value to the farmer. Of all the modes of trial, the one best suited to the unlearned farmer, is, to observe how much *fixed air* the marl gives out; and this he will learn by dissolving a little of it in diluted muriatic acid, and observing what portion of its weight it loses by the escape of this air. Thus, if an ounce loses only from 40 to 44 grains, he may conclude that the ounce of marl contained only 100 grains ot calcareous earth, and that it would be his interest to pay seven times as much for a load of lime as he must pay for a load of marl at the same distance.

Every farmer should ascertain the *nature* of his lime before he uses it in agriculture, as there are many extensive districts in England where the lime contains magnesia, which renders it injurious to the growth of vegetables.

**The theory of tanning is shortly this: After the impurities of the skins are removed, they are steeped in an infusion of oak-bark, which consists of two distinct substances, viz. the gallic acid, and the tanning principle; the latter of these combines chemically with the gelatine and albumen of the skins, and forms leather.

* Lime is frequently used by chemists in processes where there is a superabundant and injurious quantity of acid. The lime seizes the acid, and frees the solution from it, by forming with it a neutral salt.

† Gypsum, or, as it is also called, selenite or sulphate of lime when crystallized, is composed of about 33 lime, 46 parts of sulphuric acid, and 21 water.

‡ Lime combined with the fluoric acid forms those beautiful fluor spars which are brought from the mines of Derbyshire. The most usual colour of this mineral is that of a deep purple; but by exposing it to the rays of a hot sun, or to different degrees of artificial temperature, the artist has found the means of forming a suit of colours of great variety and beauty.

§ The bones of all kinds of animals are formed of lime and phosphoric acid in the proportion of 48.5 parts of that earth and 51.5 of phosphoric acid.

|| Sulphate of magnesia (the Epsom salt of commerce) is found in several mineral waters. The *bitter* saline waters generally owe their taste to this salt. That which is found in the shops is generally procured from the mothers which remain after the separation of common salts from sea-water, by subsequent evaporation and crystallization. All the salts formed with this earth are bitter, and generally very soluble.

¶ When magnesia is taken as an aperient, it ought to be in the state of carbonate of magnesia, or what is called mild magnesia. When as an absorbent to correct acidities, calcined or caustic magnesia is most proper. On several accounts it is of consequence to attend to this distinction.

**Potter's clay is a mixture chiefly of silica and alumina; the colouring earths used as pigments are mixtures either of clay and the oxides of iron, or clay and charcoal; garden mould is a mixture extremely various, sometimes containing silica, alumina, magnesia, iron, lime, and carbon; the common mill-stone is generally composed of alumina and silica; and the crumbling sandstone is a mixture of iron and silica: it is, however impossible to enumerate the endless diversity of substances which Nature offers ready formed for the use of man; for the mixtures of the earths which are found *naturally* combined comprehend most of the varieties of clay, slates, stones, gems, rocks, crystals, zeolites, quartz, flints, &c.

"†† The goodness of a soil depends upon its being able to retain the quantity of moisture which is proper for the nourishment of vegetables, and no more. Now the retentive power of a soil increases with the proportion of its alumina, lime, or magnesia; and diminishes as the proportion of its silica increases."

☞ Farmers' Directory. ☜

☞ We receive almost daily inquiries for seeds, implements, farm stock, &c. many of which it is difficult, and some of them out of our power, to answer satisfactorily. The expense of making and answering these inquiries amounts to no little in the aggregate. To remedy this inconvenience, and to render a service to the seller and buyer, we propose to insert in the extra which will accompany our February number, a Farmers' Directory, that is, to give the names, residence and business, so far as they shall be notified to us by the 10th January, free of charge, of gentlemen engaged in vending agricultural seeds, implements, and choice breeds of farm stock, in whatever state they may reside. As for example,

W. Thorburn, Albany, vends seeds and implements.

H. D. Grove, Buskirk's Bridge, Washington co. N. Y. will sell 100 Saxony sheep.

G. B. Smith, Baltimore, Md. sells Rohan Potatoes and Dutton seed corn.

To the patrons of the Cultivator, no charge will be made for this notice—to others, it will be one dollar. Advertisements, more in detail, will be inserted in a separate portion of the same sheet, on our usual terms. The advantages that are likely to result to advertisers, may be judged from the fact, that our edition is twenty thousand copies, and that our paper circulates in every state and territory in the Union, and in the Canadas.

PACKARD, VAN BENTHUYSEN & Co.

THE CULTIVATOR:

A MONTHLY PUBLICATION, DEVOTED TO AGRICULTURE.

I KNOW OF NO PURSUIT IN WHICH MORE REAL AND IMPORTANT SERVICES CAN BE RENDERED TO ANY COUNTRY, THAN BY IMPROVING ITS AGRICULTURE.—*Wash.*

VOL. V. NO. 3, WASHINGTON-ST. ALBANY, N. Y. DECEMBER, 1838. No. 10.

Conducted by J. BUEL, of Albany.

TERMS.—ONE DOLLAR per annum, to be paid in advance. Subscriptions to commence with a volume.

Special Agents.—L. & R. HILL, Richmond, Va.; BELL & ENTWISLE, Alexandria, D. C.; GIDEON B. SMITH, Baltimore, Md.; JUDAH DOBSON, bookseller, D. LANDREITH, and M. S. POWELL, seedsmen, Philadelphia; ISRAEL POST, bookseller, 88 Bowery, ALEX. SMITH, seedsman, P. WAKEMAN, office of the American Institute, Broadway, N. York; HOVEY & Co. Merchants' Row, Boston; ALEX. WALSH, Lansingburgh, and WM. THORBURN, Albany, gratuitous agents. For general list of agents see No. 12, vol. iv.

The Cultivator is subject to common newspaper postage.

☞ Price of the published volumes, 50 cents per vol. stitched—the four volumes bound together, $2.75—bound in two volumes, $3—the four vols. bound each separate, $3.25.

THE CULTIVATOR.

TO IMPROVE THE SOIL AND THE MIND.

On the Utility of Agricultural Schools.

We lay down, and intend to illustrate, the following propositions:

I. That science has become important, if not essential, to the successful prosecution of the arts of labor;

II. That a knowledge of many of its principles is particularly necessary for the improvement of agriculture;

III. That theory and practice—science and art—when made companions, reciprocally aid and improve each other; and hence,

IV. That the best way of promoting useful improvement in both, is to blend them together in schools of instruction—to teach the science and the art simultaneously, to those who are destined to manage the productive labors of our country.

Our object in introducing these propositions to the notice of the reader, is to turn the public attention to the importance of wedding science to art—of teaching both simultaneously,—in agriculture and the mechanic arts; and of enlisting the feelings, and inviting the aid, of our patriotic citizens, which we would fain hope might embrace no inconsiderable number of our statesmen, to the establishment of schools of scientific and practical agriculture.

In the discussion of the subject, we shall avail ourselves of the opinions of some of the most eminent men of the age. Although most of the quotations we shall make, may have a special reference to the mechanic and manufacturing arts, they apply with equal force to the art of agriculture.

It is self-evident, that if an individual—be he a manufacturer, a mechanic or a farmer—can, in consequence of new modes of applying and economizing labor, afford to sell his goods or his farm products, for a third less price than his neighbor—it is self-evident, we say, that such an individual possesses a decided advantage—that he will command the market—will grow rich, while his neighbor must grow poor—and that the disparity in the condition of the two, under like prudent management, will go on progressively increasing. It is precisely with communities and nations as it is with individuals. The country which produces the cheapest and best manufactured goods, or the best and cheapest agricultural productions, will ever possess a decided advantage in the market of nations—will monopolize the profits of commerce, and become opulent and powerful—while her rivals will sink as she rises, and become poor and dispirited. So true is it, that the prosperity of a country depends essentially on the extent and economical management of its productive labor. The productive labor of our country is performed principally by the agricultural, mechanic and manufacturing classes.—Hence, whatever tends to increase the amount of our domestic productions, or to cheapen their cost, has a direct tendency to benefit all classes—to increase the aggregate wealth of the state, and to multiply the comforts and enjoyments of its inhabitants.

This brings us to the consideration of our first proposition, *that science has become important, if not essential, to the successful prosecution of the arts of labor.*

But first let us inquire, *what is science?* Sir J. J. F. Herschel says,—"Science is the knowledge of many, orderly and methodically digested and arranged, so as to become attainable by one. The knowledge of reasons and conclusions constitute *abstract*, that of causes and their effects, and of the laws of nature, *natural science.*"[*] It is to the latter of these branches of science that our remarks will principally refer.

Half a century has produced a wonderful revolution in most of the arts of labor. Old and tedious processes have been superseded by the application of science, and by inventions which the rays of science have enkindled into being. The elements—fire, water and air, have been brought more under human control, rendered more subservient to human wants, and are applied, to a prodigious extent, as substitutes for human labor. Science itself has advanced in improvement and usefulness, with accelerated speed; and the processes of the manufacturer and artisan are now almost wholly regulated by its laws; and it is progressing in new discoveries with rapid pace. "Indeed, such is the quickening power of science, that it is scarcely possible, that its simplest germ should be planted in the human mind, without expanding into a healthy growth. It generates, as it moves on, new thoughts, and new inquiries, and is forever gathering without exhaustion, and without satiety. The curiosity which is once awakened by it, never sleeps; the genius, which is once enkindled at its altar, burns on with unextinguishable flame."[†] The consequence of this accelerated progress in scientific knowledge, and its more general application to the arts of labor, has been, that our manufacturing operations have been simplified, their labor abridged, and their products improved and cheapened. And wherever the principles of science have been applied to agriculture, the change has been equally great and salutary. But agriculture, from its modest pretensions, its humble condition, and, we are sorry to add, from a limited knowledge and rooted prejudice, in most of those who conduct its details, has been the last to profit, and has profited the least, from the general discoveries and improvements of the age. Practical farmers are seldom men of scientific knowledge, and scientific men seldom descend to the drudgery of practical agriculture. In the work shops, science and art have long been companions, and have mutually profited by each other's counsel and aid. When they shall combine their labors in the field, not only will agriculture double her products, but useful knowledge will be diffused, prejudice will be eradicated, and the husbandman will rise, in the scale of society, to that independent position which our constitution and laws have assigned to him, and which the perpetuity of our political institutions require he should occupy.

Our second proposition is, *that scientific knowledge is particularly essential to the improvement of agriculture.*

The sciences which have been principally instrumental in improving the manufacturing and mechanic arts, are chemistry, and those which relate to mechanical philosophy. A knowledge of these is equally important in the business of agriculture. Chemical knowledge is essential to a correct ascertainment of the properties of soils—of lime, marl and other fertilizing matters—a knowledge of which would often save useless expenditure, and ensure certainty of results. It is also beneficial in conducting economically a great many operations on the farm, and in the kitchen. Even

"The farm-servant," says Lord Brougham, "or day-laborer, whether in his master's employ, or tending the concerns of his own cottage, must derive great practical benefit,—must be both a better servant, and a more thrifty, and therefore a more comfortable cottager, for knowing something of the nature of soils and manures, which chemistry teaches, and something of the habits of animals, and the qualities and growth of plants, which he learns from natural history and chemistry together. In truth, though a man be neither machanic nor peasant, but only one having a pot to boil, he is sure to learn from science lessons which will enable him to cook his morsel better, save his fuel, and both vary his dish and improve it. The art of good and cheap cookery is deeply connected with the principles of chemical philosophy, and has received much, and will yet receive more, improvement from their application. Nor is it enough to say, that philosophers may discover all that is wanted, and may invent practical methods, which it is sufficient for the working man to learn by rote, without knowing the principles. He never will work so well if he is ignorant of the principles; and for a plain reason:—if he only learns his lesson by rote, the least change of circumstances puts him out. Be the method ever so general, cases will always arise in which it must be varied in order to apply; and if the workman only knows the rule, without knowing the reason, he must be at fault the moment he is required to make any new application of it. This, then, is the first use of learning the principles of science: it makes them more skilful, expert and useful in the particular kinds of work by which they are to earn their bread, and by which they are to make it go far and taste well when earned."[*]

A knowledge of the principles of mechanics is also important to the farmer, to enable him to judge of the relative value of farm implements, to detect their faults, and to correct them. But the business of the farm embraces a wider scope—it embraces the whole range of natural science—the earth, the air, the water, and the various tribes of domestic animals and cultivated plants come within its purview.

"The Creator of the universe," says Gov. Everett, "has furnished us the material [for useful scientific investigation]; it is all around us, above and beneath us; in the ground under our feet; the air we breathe; the water of the ocean and the fountains of the earth; in the various subjects of the kingdoms of nature. We cannot open our eyes, nor stretch out our hands, nor take a step, but we see, and handle, and tread upon the things, from which the most wonderful and useful discoveries and inventions have been deduced. What is gun-powder, which has changed the character of modern warfare? It is the mechanical mixture of some of the most common and least costly substances. What is the art of printing? A contrivance less curious as a piece of mechanism, than a musical box. What is the steam engine? An apparatus for applying the vapor of boiling water. What is vaccination? A trifling ail, capable of protecting human life against one of the most dreadful maladies to which it is exposed.

"And are the properties of matter all discovered? its laws all found out? the uses to which they may be applied all detected? I cannot believe it. We cannot doubt, that truths now unknown are in reserve, to reward the patience and the labors of future lovers of truth, which will go as far beyond the brilliant discoveries of the last generation, as those do beyond all that was known to the ancient world. The pages are infinite in that great volume, which was written by the hand divine, and they are to be gradually turned, perused, and announced, to benefitted and grateful generations, by genius and patience; and especially by patience; by untiring, enthusiastic, self-devoting patience. The progress which has been made in art and science is indeed vast. We are ready to think a pause must follow; that the goal must be at hand. But there is no goal; and there can be no pause; for art and science are in themselves progressive. They are moving powers, animated principles: they are instinct with life; they are themselves the intellectual life of man. Nothing can arrest them, which does not plunge the entire order of society into barbarism. There is no end to truth, no bound to its discovery and application; and a man might as well think to build a tower, from the top of which he could grasp Sirius in his hand, as prescribe a limit to discovery and invention.

"Never do we more evince our arrogance, than when we boast of our knowledge. True science is modest; for the keen, sagacious eye discerns that there are deep, undeveloped mysteries where the vain sciolist sees all plain. We call this an age of improvement, as it is. But the Italians in the age of Leo, and with great reason, said the same of their age; the Romans, in the time of Cicero, the same of theirs; the Greeks, in the time of Pericles, the same of theirs; and the Assyrians and Egyptians, in the flourishing periods of their ancient monarchies, the same of theirs. In passing from one of these periods to another, prodigious strides are often made; and the vanity of the present age is apt to flatter itself, that it has climbed to the very summit of invention and skill. A wiser posterity at length finds out, that the discovery of one truth, the investigation of one law of nature, the contrivance of one machine, the perfection of one art, instead of narrowing, has widened the field of knowledge still to be acquired, and given, to those who come after, an ampler space, more numerous data, better instruments, a higher point of observation, and the encouragement of living and acting in a more intelligent age. It is not a century since the number of fixed stars was estimated at about three thousand. Newton had counted no more. When Dr. Herschel had completed his great telescope, and turned it to the heavens, he calculated that two hundred and fifty thousand stars passed through its field in a quarter of an hour!"[†]

"It is a curious fact, that objects, at once the most familiar and most useful, are apt to be the last on which we bestow careful investigation and reflection. The great elements of physical nature, earth, air, heat and water, the very instruments by which we live, move, and have our being—how seldom do even these excite more than a passing notice. We till the soil, indeed, for it is the fertile parent of our daily bread; yet we rarely look beyond the surface to unfold the mysteries that lie beneath. The air is inhaled at every breath, yet we care not whither it cometh, or whither it goeth. The principle of heat is the supporter of animal and vegetable life throughout the universe; yet, though it greets us each morning with the rising sun, and calls upon us from every shining hill-top for admiration, how rarely do we think of it but as a mere matter of course. And water—how wonderful, how beautiful, how useful, how seldom do we regard it but as the vulgar instrument of daily comfort or daily necessity!

---

[*] Nature and advantages of the study of the physical sciences.

[†] Judge Story's discourse before the Mechanics' Institute of Boston.

[*] Library of Useful Knowledge.

[†] Importance to practical men of scientific knowedge.

"All this is susceptible of easy explanation. Familiarity breeds contempt in more ways than one. Whatever is new and rare excites curiosity and invites attention; while, on the other hand, commonness begets indifference. We are apt to imagine that *whatever is familiar is thoroughly understood;* while things which are new are fancied to possess properties which do not appear upon the surface. A drop of water is not less beautiful or less wonderful than a diamond, yet who stops to ponder over the one, or fails to pause and gaze with admiration on the other? Thus it is that the useful, the beautiful, the truly wonderful, are neglected, because they are common, while we eagerly run after more glittering toys, because they are rare."—*Fireside Education.*

How well do these remarks apply to the very *common* business of agriculture! It is too common a concern to arrest the attention of those who are not immediately interested in its labors; and even the practical farmer, we are sorry to add, too often *presumes* he understands it thoroughly, merely on the ground, that he has long been familiar with its details. And yet it is the great business of our country—the basis of its independence and wealth, and the main safeguard of its freedom. It is a business susceptible of being vastly improved by modern science; and yet we have no public means of extending to it this important aid. We have schools in abundance—we believe we may with propriety say in excess—for it is rather by their quality than their number that we should judge of their usefulness—to teach the higher branches of learning to the few—to the non-producing classes,—tending to create artificial distinctions, where none should obtain but such as are rewards to merit—and these schools have been established and maintained by a public expenditure of three millions of dollars in this state.

"The light of heaven is not more the right of all," says a late writer, "than the light of knowledge; and a scheme to appropriate to a privileged class of persons the glorious rays of the sun, while all beside are to be wrapped in the chill shadows of night, would not be more a conspiracy against the natural rights of man, than is any system which would shut out from the view of the people at large, the intellectual light implanted by education."

Now we insist, that with the advantages of learning that have been extended to the comparatively small unproductive classes, coupled with the practical instruction which would be obtained in agricultural schools, our agriculture would in a few years be made to double its products, agricultural labor would be more honored and more inviting, and a corresponding improvement would be witnessed in the intellectual and moral condition of society. Although a *common* employment, it is an *indispensable* one; and although mere animal power may *perform*, it requires mind—science—to *direct* its operations, with usefulness and profit.

"Within a few years," says the author last quoted, "society seems to have received a new impulse, and the conviction, that not only the happiness of private life, but the security of our institutions, depends upon the diffusion of knowledge, seems to pervade all classes. Nay, the opinion has gone abroad, that education is the only lever which can lift a community from the degradation to which the tendencies of human nature would drag mankind. If you would correct a prevalent vice, if you would purify the fountains of society, it is admitted that you must begin with the young. It is difficult to change the character of those who have reached mature age, and become the subject of established habits. The oak which has struck its roots deep and strong into the soil, and whose branches are hardened by time, cannot easily be bent to new forms. It is the sapling alone that submits to be trained at the will of the cultivator."

Wherever science has been applied to agriculture, and blended with the labors of the field, it has proved of great advantage. To illustrate its utility, Lavoisier, the great French chemist, undertook the management of a farm, and in four years he doubled its products, and more than doubled its profits, by the aids which science contributed to its culture. Von Thaer, who is at the head of the great agricultural school of Prussia, has produced, it is believed, still more favorable results. The students of the Hoffwyl agricultural school of Fellenburgh, obtain great salaries all over Germany, as managers of farms and landed estates. So manifest have become the advantages of science to the improvement of agriculture, that schools of practical and scientific instruction have been established in the German states, in France, Russia and in Ireland. Indeed, small as is the smattering of agricultural science among our farmers, we are daily profiting by it; and individual farms and districts evince a superiority of culture, in proportion as its principles are recognized and judiciously applied.

Our third proposition is, *that theory and practice—science and art—when acting in concert, reciprocally aid and improve each other.*

"It was not until some fortunate discoveries in the arts had led to opulence," says Judge Story, "that scientific men began to surrender their pride, and to devote themselves practically to the improvement of the arts. The first great step in modern science was to enter the work-shop, and superintend its operations, and analyze and explain its principles, and the benefits derived from this connexion have already been incalculable both to art and science. Each has been astonishingly improved by the other; and a hint derived from one has often led to a train of inventions and discoveries, the future results of which are beyond all human power to measure. Thus, dignity and importance have been added to both. The manufacturer, the machinist, the engineer, the chemist, who is eminent in his art, may now place himself by the side of the scholar, the mathematician and the philosopher, and find no churlish claim for precedency put in. His rank in society, with reference either to the value of the products of his skill, or the depth of his genius, sinks him not behind the foremost of those, who strive for the first literary distinction. This fortunate change in the public opinion, which has made it not only profitable, but honorable, to pursue the mechanical arts, is already working deeply into all the elements of modern society."

"It may now be said with truth, that, in a general view, science precedes art; that is, the improvements which are made in art, arise more often from an exact investigation of principles, than from bare experiments and accidental combinations. Principles suggest the experiment, rather than experiment the principles. In the most important branches of manufactures, where skill is constantly in demand, and economy in operation is so indispensable, and competition is universal, there is now a perpetual tasking of the wit of man to invent some cheaper, thriftier, or neater combination. Something to increase the velocity, and uniformity of motion, the delicacy and certainty of spinning, the beauty or fineness of fabrics, the simplicity or directness in application of power, or something to ascertain or separate the worthless from the valuable in materials, is the ambition of a thousand minds at the same instant; and the project holds out ample rewards to the fortunate discoverer."

"It is so obvious that he who is engaged in the practice of an art, must, with equal advantages, be far better qualified to improve and perfect its operation, than he who merely theorizes without any knowledge of practical difficulties, that it is matter of surprise, that it should have been so long overlooked."

"I might remark, that genius and talent are limited to no rank or condition of life. They have been distributed by the bounty of Providence, with an equal hand, through every class of society. They are among those gifts, which poverty cannot destroy, or wealth confer; which spring up in the midst of discouragements and difficulties, and, like the power of steam, acquire new elasticity by pressure; which ripen in the silence of solitude, as well as in the crowded walks of society; which the cottage may nourish into a more healthy strength, than even the palace or the throne. The most formidable enemy to genius is not labor, but indolence; want of interest and excitement; want of motive to warm, and of object to accomplish; ignorance of means leading to indifference of ends. Hence it is, that the very highest and very lowest orders of society, often present the same phenomena—a fixed and languishing disease of the intellectual powers, where curiosity wastes itself in trifles, and a cold listlessness, brooding over the thoughts, lets fall a preternatural stupor. Their misfortune is that so beautifully touched by the poet—

"But knowledge to their eyes her ample page,
"Rich with the spoils of time, did ne'er unroll,"

"I might remark, in the next place, that the rewards of science are most ample, whether they be viewed in reference to personal enjoyment, to rank in society, or to substantial wealth."

"It is from considerations of this nature;—that what has been, must continue to be; that art is never perfect, and nature inexhaustible; that science, while it is the master of art, is itself ultimately dependent upon it; that the intellectual power grows up in all stations, and in all soils; that, all other circumstances equal, he who knows and practises, must forever take the lead of him who merely knows, and has none of the skill to apply power, or the practical sagacity to overcome difficulties; that he, whose interests are indissolubly connected with his science, and who feels at every turn the animating impulse of reward, as well as the pleasure of speculation, and the desire of fame, has more enduring and instant motives for exertion, than he who merely indulges his leisure, or his curiosity;—it is, I say, from these considerations, that when the artizan and the mechanic [and the farmer] shall have become instructed in science, the inventions of this class will have become more numerous, more useful, more profitable, than those of any other class, and even perhaps of all other classes of society.

"What an animating prospect does this afford! What noble ends to poor, neglected suffering genius! What constant comfort to cheer the hard hours of labor, and the heavier hours of despondency! Much less of success in life is really dependent upon accident, or what is called luck, than is commonly supposed. Far more depends upon the objects which a man proposes to himself; what attainments he aspires to; what is the circle which bounds his visions and his thoughts; what he chooses, not *to be educated for*, but *to educate himself for;* whether he looks to the end and aim of the whole life, or only to the present day or hour; whether he listens to the voice of indolence or vulgar pleasure, or to the stirring voice of his own soul, urging his ambition on to the highest objects. If his views are low and grovelling; if the work-shop [or farm], in its cold routine of duties, bounds all his wishes and his hopes, his destiny is already fixed; and the history of his whole life may be read, though the blush of youth still linger in his cheeks. It is not a tale merely twice told; it has been told for millions. If, on the other hand, he aspires to be a man, in dignity, independence, spirit and character, and to give his talents their full scope and vigor; if, to a steady elevation to the practice of his art, he adds a scientific study of its processes and principles, his success is as sure as any thing on this side of the grave can be."*

"The distinct purpose [of the Boston Mechanic Association] is," says Mr. Webster, "to connect science, more and more, with art; to teach the established, and invent new, modes of combining skill with strength; to bring the power of the human understanding in aid of the physical power of the human frame; to facilitate the co-operation of the mind with the hand; to augment convenience, lighten labor and mitigate toil, by stretching the dominion of mind, farther and farther, over the elements of nature, and by making those elements, themselves, submit to human rule, follow human bidding, and work together for human happiness."†

We have endeavored to show, that science is essential to the successful prosecution of the arts, in order to sustain our rank in the rivalship of nations, to maintain our commercial advantages, and to ensure our progress in enterprise, wealth and the other elements of national prosperity;—that science is particularly necessary to our improvement in agriculture, the great business of our country, the stay of its commerce, the principal source of its wealth, the bond of its union, and the security of its freedom; and that science and art—theory and practice—when combined, reciprocally aid and improve each other. This brings us to our fourth and last proposition, viz.

That the best way to promote useful improvement in science and art—the great instruments of wealth and power,—is to teach both, simultaneously, to those who are destined to manage the productive labors of our country.

We shall confine our remarks, on this branch of the subject, to the arts of agriculture and agricultural mechanics.

That a knowledge of the leading principles of natural science, is essential to agriculture, in its most improved and profitable management, is evidenced in the established utility of schools of scientific and practical instruction, in European countries, and in their continual multiplication; and in the improvements which science has effected in our own agriculture, wherever its principles have been coupled with intelligent practice. This fact being conceded, the question presents, how are our young farmers to acquire the requisite knowledge? our common schools do not teach it; nor does the farm afford the requisite means of instruction. And as for our colleges and academies—

"Generally speaking," says Gov. Everett, "even now, all actual instruction in the principles of natural science is confined to the colleges; and the colleges are, for the most part, frequented only by those intended for professional life; but it does not seem a proper arrangement, that none but those intended for the pulpit, the bar, or the profession of medicine, should receive instruction in those principles, which regulate the operation of mechanical powers, and lie at the foundation of complicated machinery; which relate to the navigation of the seas, the smelting and refining of metals, THE COMPOSITION AND IMPROVEMENT OF SOILS, the reduction to a uniform whiteness of the vegetable fibre, the mixture and application of colours, the motion and pressure of fluids in large masses, the nature of light and heat, the laws of magnetism, electricity and galvanism. It would seem that this kind of knowledge was more immediately requisite for those who are to *construct and make use of labor saving machinery,* who are to navigate the ocean, to lay out and direct the excavation of canals, to build steam engines and hydraulic presses, and to conduct large *agricultural* and manufacturing establishments. Hitherto, with some partial exceptions, *little has been done to afford to those engaged in these pursuits that*

* Discourse before the Boston Mechanic Institution.

† Introductory lecture, before the Boston Mechanic Institution, by Hon. Daniel Webster.

knowledge, which, however convenient to others, would seem ESSENTIAL to them. There has been scarce anything which could be called education for practical life; and those persons who, in the pursuit of any of the useful arts, have signalized themselves by the application of scientific principles for the invention of new processes, or the improvement of the old, have been self-educated men."

"Neither is it intended, that the education which we recommend, should extend to a minute acquaintance with the practical applications of science to the details of every art. This would be impossible, and does not belong to preparatory education. We wish only that the general laws and principles should be so taught, as greatly to multiply the number of persons competent to carry forward such casual suggestions of improvement as may present themselves, and to bring their art to that state of increasing excellence, which all arts reach, by long-continued intelligent cultivation."*

Our young men, destined to agricultural pursuits, do not, cannot, get scientific instruction in the college; for the collegiate period of life is that in which they must acquire a practical knowledge of their business. It is only, therefore, by combining labor with study, that they can expect to profit largely by the advantages which science proffers. And in schools of this kind, not only the elementary principles of science may be learnt, but the application of these principles may be tested and illustrated in practice—and, what is of no little moment, the best practices in the art, in all its diversified branches, may be taught at the same time. Instead of seriously interfering with each other, study and labor, we have seen, being directed to a common object of usefulness, tend to enlighten, encourage and animate each other.

Children belong to the republic; that is, the public have a deep interest in the manner of their being brought up and educated—whether to habits of industry and usefulness, or those of indolence and vice. They are the materials which are to constitute the moral and political fabric of the rising generation; and every measure which has a tendency to render them intelligent and virtuous, indirectly benefits every member of the community.

"An intelligent class" remarks Gov. Everett, "can never be, as a class, vicious; never, as a class, indolent. The excited mental activity operates as a counterpoise to the stimulus of sense and appetite. The new world of ideas; the new views of the relation of things; the astonishing secrets of the physical properties and mechanical powers, disclosed to the well informed mind, present attractions, which—unless the character is deeply sunk—are sufficient to counterbalance the taste for frivolous or corrupt pleasures; and thus, in the end, a standard of character is created in the community, which, though it does not invariably save each individual, protects the virtue of the mass."

We shall close our remarks on this deeply interesting subject, with another extract from Gov. Everett's essay on the importance of scientific knowledge.

"Contemplate, at this season of the year," says he, "one of the magnificent oak trees of the forest, covered with thousands and thousands of acorns. There is not one of those acorns which does not carry within itself the germ of a perfect oak, as lofty and as wide-spreading as the parent stalk; which does not unfold the rudiments of a tree that would strike its roots in the soil, and lift its branches towards the heavens, and brave the storm of a hundred winters. It needs for this but a handful of soil, to receive the acorn as it falls, a little moisture to nourish it, and protection from violence till the root is struck. It needs but these; and these it does need, and these it must have; and for want of them, there is not one out of a thousand of those innumerable acorns, which is destined to become a tree.

"Look abroad through the cities, the towns, the villages of our beloved country, and think of what materials their population, in many parts already dense, and every where rapidly growing, is, for the most part, made up. It is not lifeless enginery, it is not animated machines, it is not brute beasts, trained to subdue the earth: it is rational, intellectual beings. There is not a mind, of the hundreds and thousands in our community, that is not capable of making large progress in useful knowledge; and no one can presume to tell or limit the number of those who are gifted with all the talent for the noblest discoveries. They have naturally all the senses and all the faculties—I do not say in as high a degree, but who shall say in no degree?—possessed by Newton, or Franklin, or Fulton. It is but a little which is wanted to awaken every one of these minds to the conscious possession, and the active exercise, of its wonderful powers. But this little, generally speaking, is indispensable. How much more wonderful an instrument is an eye than a telescope! Providence has furnished this eye; but art must contribute the telescope, or the wonders of the heavens must remain unnoticed; and it is for want of the little, that human means must add to the wonderful capacity for improvement born in man, that by far the greatest part of the intellect, innate in our race, perishes undeveloped and unknown. When an acorn falls upon an unfavorable spot, and decays there, we know the extent of the loss;—it is that of a tree, like the one from which it fell;—but when the intellect of a rational being, for want of culture, is lost to the great ends for which it was created, it is a loss which no one can measure, either for time or eternity."*

"The design of promoting the advancement of the sciences, is a far nobler object of ambition," says Lord Bacon, "than either *private* aggrandizement or *patriotism* itself. The first is vulgar and degenerate; the second, that is, the ambition of those who endeavor to raise their own country in the scale of nations, is more noble, but has not less of cupidity: but if any one should labor to restore and enlarge the power and dominion of the whole race of man over the universe of things,—this kind of ambition, if so we may call it, is without doubt more wise and dignified than the rest. Now this power of man over things is entirely founded in arts and sciences."

Culture and Propagation of the Morus Multicaulis.

The point seems to be settled, at least for the present, that in the states south of New-York, the multicaulis is to supersede all other descriptions of the mulberry for the fabrication of silk. And even in our northern latitude, many persist in saying, that it may be cultivated with great profit, and some have realized large sums from their plants and buds. The price here is now two and a half cents per bud. But we ought to repeat, that the only certain mode relied upon for preserving the plants through the winter, at the north, is either to take up the entire plant in autumn, and bury it in the ground, or to cut it off near the surface, bury the top and cover the stump. It is contended, that the sprouts which will annually spring from the plant, thus cut down, will afford more leaves than the tree would if left to grow, while the foliage is much more easily gathered. Besides this, a great gain is effected by obtaining the tops for propagating, as under good management almost every bud will produce a plant the coming season.

The interest has become so general in the increase of this plant, that directions for propagating it cannot fail of being acceptable to our readers; and we therefore sit down to give these directions, not however as derived from personal experience, but from the practice of two of the oldest and most eminent growers of the plant in the United States—Gideon B. Smith, of Baltimore, and T. S. Pleasants, of Goochland, Va. We extract these directions from the communications of these gentlemen, published in the Farmers' Register.

Mr. Smith directs as follows:

"The simplest and most common mode of cultivating the multicaulis is as follows:—Prepare the ground in the spring as for corn. Run furrows four or five feet apart as preparatory to planting corn. Then take the limbs and young wood that grew last year, cut off close to the tree, and lay them lengthwise, the but end of one limb a short distance, a foot or so, from the top end of the last laid down; cover the whole limb, with a hoe, about one or two inches deep; generally every bud on each limb will grow, and make a tree from three to five feet by autumn. The ground should be kept free from weeds and grass by cultivation, as in corn. About the last of July, it is best to take a sharp spade and separate the young trees, by driving it down midway between them; but this is not essential; they can be separated when taken up the spring [or autumn] following. The next spring they should be taken up and planted in regular form in the orchard, where they are permanently to remain. The best method is to plant them six or eight feet apart in the row, and the rows ten to sixteen feet apart—the rows running north and south, or north west and southeast. By this mode of cultivation it will be perceived, that eight or ten times as many multicaulis trees may be raised on an acre of ground as cornhills, and that, as the crop is ready for the market, (when they are raised to sell,) as early as the crop of corn, there is no reason for the extravagant prices demanded for them. They would be a very profitable crop at five cents a tree.

"There are other modes of cultivation which it may be well to describe here. When cuttings are scarce, and the loss of many of them is of much consideration, a hot-bed should be made in the usual way, and the cuttings started in it as follows:—Cut all the limbs and young wood into short pieces, with *one bud* on each; lay them flat on the surface of the hot-bed, in lines lengthwise, the ends of the cuttings a quarter of an inch apart, and the lines of cuttings two inches apart, with the bud uppermost. Then sift rich garden mould over them, half an inch deep, and put the glass frames on the beds. Every night and morning water them with a watering pot, merely enough to keep the earth moist.—They should be planted in the hot-bed one month before the usual disappearance of frost. In and around Baltimore, the first of April is the time, as frost usually disappears altogether about the first to the tenth of May, By the time the frost disappears, the plants will be about the size of cabbage plants, and may be taken out of the bed and planted in the orchard where they are permanently to grow. During the time they are in hot-beds, care should be taken in warm days to give them air, by raising the glass frames [sashes]; and if severe frosts occur, to cover the glass with straw or matting; and when they are set out in the field they should be well watered, for a few days, in the evening. The practice of propagating as above, from single buds, was first adopted by me, and followed for many years with very great advantage."

"Another method is by layers. Instead of cutting off the limbs and tops, bend the whole tree down to the ground, and cover it, limbs and all, two or three inches deep, with good mould—it would be well to turn np the ends of the limbs, so that the points are just above the ground. All the buds that are on the whole tree under ground, will generally grow, and each one make a tree by autumn, when they are to be taken up and separated. The objection to this plan is, that the young trees are apt to be too crowded, and consequently do not grow as large as when the limbs and young wood are cut off, as in the first mode; and I do not find that it is any more certain, or possesses any one advantage, over that mode. All other modes of propagating, as grafting, &c. are perfectly useless, and therefore nothing need be said about them."

The following is from letters of Mr. Pleasants to Mr. Ruffin, editor of the Farmers' Register:—

"On the subject of *one bud cuttings* of multicaulis, I can give thee my experience this year, which perhaps may be of some value. It is probably known to thee, that with scarcely any exceptions, there was a great failure in getting cuttings to start last spring. John Carter is the only cultivator I know who has succeeded well. Next to him, I place myself—but at a considerable distance in the rear. To the north, not more than one in fifteen or twenty grew. The failure was owing to a most peculiar season, for I never saw cuttings start better than mine did. An excessive drought, at the time the plants began to root, dried them up. In preparing my cuttings, out of some of the strongest and best wood, I cut 10,000 or 15,000 with one bud. The remainder had two buds. The one bud cuttings I planted to themselves, in the same sort of ground with the others, and they were all subsequently treated alike. Taking the piece at large, they stand as well as the best spot of two bud cuttings, and much better than the greater part of them. They came up with great regularity, and have come off very evenly.

"If the season is propitious, there is no reason why a cutting with one bud should not grow as well as one with two buds. A large one may be stuck deeper in the ground, and in a drought, it may be longer under the influence of moisture. But with *early planting*, I have no hesitation in relying upon my good one bud cutting; and early planting, by the way, is more or less important to the success of every mode. I have never taken up my multicaulis so early in the spring, but what I found the buds started, and the little rootlets in the act of being thrown out. The growth must, therefore, be checked by exposure to the air and transplanting.—From my observations, the conditions I would recommend (and which I rely on so fully that I intend to practise them,) in order to insure success to one-buds, are as follows: Preserve the plants during winter in a cool place, not exposed to the sun. Let the ground be prepared, so that the planting be may commenced as early as the season will permit; if in February the better, and at all events early in March, [in Virginia.] The soil should not be so light or sandy as to become thirsty very soon. Let the cuttings be prepared by separating midway between the joints, and stick them deep enough for the bud to be covered from an inch to an inch and a half, according to the texture of the soil. The bottom of the slip will then be about two and a half inches beneath the surface, a depth to which the ground seldom becomes entirely dry in the early part of the spring—and if there be any choice of ground in the lot, select for single buds that part which lies the lowest. With these precautions' and, above all, *early* planting, no failure can, in my opinion, ensue. By a strong cutting, I mean one taken from the larger part of the main stem, of a vigorous stem, and those near the base of thrifty lateral branches. Some days ago, I removed the earth from a number of my single bud plants, for the purpose of examining them carefully. I found some smaller than I intended to plant, but the trees were as large as those from the largest cuttings. My plants will this year yield per cutting about forty buds, on the average, perhaps more; and the most of them grow on a thin shallow soil, that never was manured. It is the opinion of many men of judgment, that the present prices will be nearly or quite sustained another year."

In cutting off the laterals, or branches, for propagation, Mr. Pleasants recommends, that the lower bud on the branch be left to produce a new branch another season. He also thinks fall planting of the buds will succeed best, and intends to try it.

The editor of the Register gives some additional facts in regard to propagation, from Mr. Sydney Weller, of N. Carolina. It is well known that the wood ta the terminal points of some of the branches do not ripen early enough to render them sound and hardy, and that the cold of winter therefore destroys them. Mr. Weller cuts the branches after the occurrence of the first slight frost, and buries them. The consequence is, that the tender, half-ripened wood matures in the soil, and the buds all grow in the spring.

In propagating by buds, upon light soils, it would evidently be of service to tread the earth upon the buds, after they are covered, as we do upon garden seeds, with a view to render the ground more compact, and prevent excess of evaporation.

Another mode of propagating is, first to take up the entire plant, particularly when it has grown but one year, and to bury it horizontally, roots and all, in the manner practised with branches. It is said, that being thus connected with the roots, the buds and plants which they produce, are not liable to be injured by drought.

* Essay on the importance of scientific knowledge.

* Essay on the importance of scientific knowledge.

The Farmers' Garden.

KITCHEN DEPARTMENT.

In the enumeration of articles to be cultivated in the garden, for consumption in the family, other than the fruits we have spoken of, we shall notice those which are of most easy culture, suitable to our climate, and of substantial use in household economy; and shall notice them in alphabetical order.

1. Asparagus. This is one of the most valuable products of the garden, both on account of the little labor which it demands, and the rich and abundant returns it makes for the table, or for market: for after a bed of it is once established, it is rendered productive for many years with but little labor. The ground should be dug deep, well manured and pulverized, and laid off in beds of four feet or more, with two feet alleys between them. It is preferable to trench the ground, and to throw in manure at the bottom of the trench. Sow the seeds thinly in drills a foot asunder, and two inches deep; and when the plants are well established, thin them to eight or twelve inches asunder. If plants are to be used,—and they are to be had at the nurseries at 50 to 75 cents the hundred,—gather from four to six inches of the earth from the top of the beds, into the alleys, place the plants at twelve inches distance each way, then cover them with the dirt taken from the surface. The asparagus from seed, if the soil and management are good, may be cut the third year; from transplanted roots generally the second year. The drier the bottom of the bed, the deeper may the planting be made. The beds should be kept free from weeds, and in autumn it is advisable to cover them with coarse dung, which should be taken off in the spring, and the surface well loosened with a fork. With care an asparagus bed will last twenty years; Cobbett says three generations. We are acquainted with but one variety, and that is good enough. The seed may be sown in the spring—the plants put out then or in autumn. In our latitude asparagus is fit to cut from the 15th to the 25th April; and the cutting may be continued till the middle of June.

2. Balm, is a perennial plant, purely medicinal. There are two varieties, the high and low. A few plants of each in the border are desirable.

3. Basil is a sweet pot-herb, and is dried for winter use. It is an annual, and the seed should be sown in very fine earth.

4. Beans. What are with us generally termed English beans (*Vica faba*) are not much cultivated, not proving productive in our hot summers. They should be planted in April, where they will be most protected from heat, in rows four feet apart, and the plants four inches apart. Of the kidney, or common bean, there are a great many varieties, both of bush sorts and runners. The early sorts may be planted late in April or early in May, the general crop the 20th May, and even in July for pods to be preserved during winter. Of the runners, the Lima, horticultural and sieva (formerly called case knife beans) are the most esteemed. The Lima should be planted as early as the warmth of the soil will permit. Bush beans are ordinarily planted in drills, two feet apart, or in single drills upon the edges of the plats or borders. The pole beans may be planted in hills, two and a half to three feet each way. Beans not only serve a valuable purpose as food in the summer, but are useful in winter, either after they have ripened, or when gathered green, and pickled in the pod, or dried in the berry. This is particularly the case with the Lima, when shelled green and dried. Most sorts of the bean like a light, dry, but rich soil.

5. Beets. Though not generally raised by farmers, the beet is a valuable root for the table, and for all kinds of farm stock. Their nutritive properties are indicated by the sugar they afford—their profitable culture by the great product which they yield. This is one of the good things of which there is no danger of having too much; and yet a rod of ground will supply a family. Sow the turnip rooted for early use, and the blood variety for winter. The beet is sown in drills, at least a foot apart, and the plants should be thinned to six inches. Great size is not desirable, as those of medium growth are found to be preferable for flavor and nutritive properties. Harvest the beet as soon as it has done growing, as it deteriorates, if suffered to stand longer in the ground. It is a good practice to steep the seed in tepid water, for 24 to 48 hours before it is deposited in the ground, and to press the earth upon it afterwards.

In preserving beets, and most other roots, for winter use, they should be kept from heat and too much air. After they are freed from external moisture, they should either be secured in pits, or packed, or at least covered, in the cellar with dry earth or sand.

6. Brocoli is but little cultivated, though it is a delicious vegetable. It belongs to the cabbage family, and is managed like it. The head is boiled and eaten like the cabbage. There is a white and a red, the latter the most certain crop. It comes to maturity for eating about as soon as cabbage, and may be sown very early, for early use, and the last of May for autumn use.

7. Bene. This is highly esteemed, not only for the oil which is afforded by its seeds, but as beneficial in allaying local inflammation, particularly of children, in the bowel or summer complaint. A leaf of this plant immersed in a tumbler of water, transforms the liquid into a thin jelly, inodorous, and without taste or colour, which children will drink freely.

8. Cabbage. Although this is a common garden production, very little attention is given to varieties, or to a succession for the table; and size is regarded rather than quality. Cabbages may be in use ten or eleven months in the year. The early sorts, if the plants are reared in a hot-bed, may be fit to eat in July, and Savoys keep good till May. Every farmer understands the culture of this plant; but few have experienced the advantages of transplanting them *twice*, i. e. first from the seed bed where they are generally crowded, and have crooked stems, into a bed of rich mould, at four to six inches apart, which is termed *pricking out;* and secondly, when they have there become thrifty, and of good size, into the place where they are to head. A hundred may be pricked out with a dibble in a few moments, and the plants are rendered doubly valuable by it. The dibble is a sharp pointed stick, with which a hole is made for the plant, and, when it is inserted in it, the earth is pressed to the root. The Savoy is the most delicate, and keeps best for late spring use. Cabbages keep well during winter in a trench, the heads down close together, and roots even with the surface, covered merely with earth; but they should be thus buried in a dry soil, and as late as possible before winter sets in. Cobbett recommends, as the best mode of preserving cabbages in winter, as follows:

> "Lay out a piece of ground four feet wide, and as long as is required for your cabbages. Dig on each side of it a little trench, a foot deep, and throw the earth upon the four feet bed. Make the top of the bed level and smooth. Lay some poles, or old rails, at a foot apart, long-ways, upon the bed. Then put some smaller poles, or stout sticks, crossways, upon the rails or poles, and put these last at five or six inches apart. Upon these lay corn-stalks, or broomcorn-stalks, or brush of trees, not very thick, but sufficiently thick to cover all over. Then, just as the frost is about to lock up the earth, take up the cabbages, knock all dirt out of their roots, take off all dead or yellow looking leaves, and some of the outside leaves besides; put the cabbages, head downwards, upon the bed, their roots sticking up; and cover them so thick with straw as for the straw to come up nearly to the root of the cabbage. Do not pack them quite close. It is better if they do not touch each other. Lay some bits of wood, or brushwood, to prevent the straw from blowing off. If the frost catch you, before you have got the cabbages up, cut them off close to the ground, and let the stumps, instead of the roots, stick up through the straw. Out of this stack you will take your cabbages perfectly green and good in the spring, when the frost breaks up; and to this stack you can, at all times, go, in the winter, with the greatest facility, and get your cabbages for use, which you can to no other species of conservatory that I ever saw or heard of. The hollow part below the cabbages takes away all wet that may come from occasional rains or melting of snows, and the little ditches on the sides of the bed keep the bed itself free from being soaked with wet. Even if deep snows come and lie for months, as in Nova Scotia, New-Brunswick and Canada, it is only removing the snow a little, and here are the cabbages always fresh and good."

We have no doubt of the utility of this mode; and to those who raise cabbages for winter and spring market, when the price is always high, Cobbett's directions are particularly worthy of attention.

9. Kale, is of the cabbage family, the leaves and sprouts of which are boiled in winter and spring as greens. There are several kinds, none of which that we have seen stand well our northern winters, which is required to have them useful. We have not seen the Siberian, recommended by Mr. Garnet. We might presume, from its name, that it would prove hardy with us.

10. Kale (Sea) has been highly extolled as a substitute for asparagus, and as coming earlier in use than that plant. We have tried it, but can say nothing in its favor, except it requires more labor than it is worth.

11. Camomile is a medicinal herb of great use. There is a single and double flowering variety. It stands our winters tolerably well. A small root will increase to a bed in a season. The flowers should be gathered ere they begin to fade. The stems, gathered and dried, possess in a great measure the virtues of the flower.

12. Capsicums. (peppers)—The large squash variety is used for pickles, the small bird kind for sauce. The seed should be sown early in fine earth. Where there is a hot-bed, it is well to sow in this. Thin the plants to eight inches.

13. Carrot. This, like the beet, is never lost to the grower; as it is readily eaten by most domestic animals; and is deemed equal to oats for horses. Sow in drills, in May, one foot apart, press the earth upon the sown seed, and thin the plants to five or six inches. The Altringhan and orange varieties are the best. ☞ The ground for all tap-rooted vegetables should be dug deep. A top-dressing of ashes is excellent for the carrot.

14. Cauliflower. Although this plant is considered a delicacy, resembling much the brocoli, yet it is seldom brought to perfection with ordinary care. The French call it the flowering cabbage; and it may be managed like the cabbage, except that it demands much moisture and a rich soil.

15. Celery is yet very little cultivated in the farmer's garden. Fifty plants will suffice for an ordinary family, and these may be raised in a trench of twenty-five feet. The seed should be sown early, if in a hot-bed the better, and the plants pricked out, as directed for cabbage. In July dig a trench a foot deep and a foot wide. Lay the earth upon the sides, or if more than one trench is dug, between the trenches, which should be five feet apart. Put into the trench rotted dung, or compost, dig it in, and set out your plants, six inches apart. As the plants progress in growth, draw the earth from the sides to the stems, taking care not to cover the heart, or central shoots; and continue this earthing, once in a week or ten days, till late in autumn, using as you have occasion. If covered so as to exclude wet, celery may be kept in the ground all winter; but the common mode is to preserve it in the cellar, by packing the roots in dry earth, or planting them in a trench. Some persons, who esteem the roots, plant on the surface of the ground, and do not earth the plants till they are removed to the cellar for winter use. These keep much the best.

16. Chives, often called sives, are perennial, and are often employed as edgings to walks. The tops are used in the spring in salads.

17. Corn. Early varieties, and particularly sweet corn, may be planted in the garden, for table use. Sweet corn may be preserved, when full grown, for winter use, and with dried beans, can be made into *succatash* at all seasons. Pick the corn when full grown, husk and place the ears in an oven, heat moderately; then take the corn from the cob, finish the drying process in the sun or an airy room, and pack it away for use. It will keep years.

18. Cress, or pepper-grass, is a grateful salad, alone or with lettuce. Sow in drills very thick, and cut before it comes into rough leaf.

19. Cucumber. For an early crop, where a hot-bed is not used, dig holes in a warm part of the garden, put into each, half a barrow full of hot unfermented stable dung; cover the dung with six inches of good mould, and plant your seeds. Small boxes, with two to four lights of glass, are advantageously used to protect cucumbers and melons in May and June, both from cold and insects; and when once prepared may be preserved for years. The main crop, for pickles, &c. may be planted the first week in June.

20. Dandelion, although considered a pest, affords one of the earliest and best greens. It is cultivated in many gardens for this use. It may be slightly covered with earth in autumn, and in this way it becomes finely bleached. The French esteem it as a salad.

21. Dock. The species called Patience Dock, of early growth and broad leaf, is often cultivated as a green. Six feet square upon a warm border will afford a great supply.

22. Egg plant. The fruit of this plant is highly esteemed by many. The seed should be sown early, if in pots in a hot-bed the better, and transplanted early in June into the open ground. Put the plants two feet apart each way. Care must be taken to protect the young plants from the black flea.

23. Endive is principally cultivated as a winter salad. Sow early for summer crop, and the middle of July for winter use. To bleach endive, which adds to its value, gather all the leaves up with your hand when they are dry, draw them into a conical form, and tie them round with matting or a soft string. When they have remained in this state about a fortnight, they will be bleached and fit for use. The curled sort is the handsomest, the plain the best. For winter or spring use, the plants are taken up in the fall, with balls of earth, and placed in light earth in a cellar.

24. Garlick, although seldom used as food by Americans, is nevertheless often in demand for medicinal uses. It is perennial and hardy. A few cloves or roots will occupy but a foot of ground and may prove serviceable.

Dairy Management in Scotland.

We have before us the report of the committee of the Highland Society of Scotland, by whom premiums were awarded for butter and cheese. The report particularizes the deviations from ordinary practice of the successful competitors; and without affirming that these deviations were really instrumental in securing success, they deem them entitled to particular notice. We shall notice such of these details as seem most likely to be serviceable to our readers; and it will be remembered that they come from the successful competitors.

CHEESE MAKING.

Mr. Harvie keeps his cheese-house at the regular temperature of 78° Fahrenheit, throughout the whole season of cheese making, and executes the different processes of manufacture without delay. He thinks it impossible to produce cheese of fine quality and taste, without the use of the thermometer.

Mr. Harvie thus describes his modes of making double Gloucester, Stilton and Wiltshire cheese.

"*Double Gloucester cheese* is made from milk as taken from the cow, carefully put through a scarce [strainer,] into a tub of sufficient size for the cheese to be made. In the extreme of summer heat, the milk from the cow may be found too warm. It will be so if above 94°, but the temperature may be easily brought down by the addition of cold skimmed milk. The rennet is then applied, and, if good, the curd may be expected to coagulate in 20 or 25 minutes. The whey is taken away with a skimming dish, and the curd pressed with the hand till it becomes firm. The curd is then broken down with a double cheese knife, and put into a drainer with a gentle pressure above it. The curd is improved by washing with boiling water instantly drained off. The curd is then broken down as small as possible, salted, wrapped in a cloth, put into the cheese vat, [cheese hoop] and sent to the press. The cloth is regularly changed until it remains dry under the press, which is the only criterion to shew when the curd is sufficiently pressed. With the most expert cheese-makers, it may happen, that whey remains in the centre of the curd, which, if not quickly observed and removed, will crack and deform the cheese. An experienced person can detect this fault at an early stage, and by applying, for a short time, the cheese over the steam of a boiler, the whey will ooze out, and by the immediate application of the press, it may be all squeezed out. After the pressing is over, the cheese should be laid on a dry shelf, with a little fog or meadow hay under it to expedite the extraction of damp. The cheese should be turned daily, and well rubbed with a dry cloth, but after getting firm, once a week will be sufficient. It will be found a great conveniency to have a spare press, and cast iron presses are far preferable to others, as the pressure can be regulated in them at pleasure.

"*Stilton cheese* is made by mixing the evening's cream with the morning's milk, in the proportion of one gallon of cream to three gallons of sweet milk, and treated as above.

"*Wiltshire cheese* is made with new milk and cream, in the proportion of one quart of cream to two gallons of new milk, and treated as above."

Mr. Mackay, who received the first premium for his *skimmed milk cheese*, thus details his process—

"The cheeses were made from skimmed milk, one-half of which had stood 24, and the other half 12 hours, when both were carefully creamed, and one-half heated to a degree that will make the whole the requisite temperature. The milk, when thus prepared, receives the steep or rennet. A gill of rennet, made from a calf's stomach, will be sufficient for a quantity of milk that will make a cheese of forty pounds. After the rennet is put in, the milk must stand until it be all properly curdled. The curd is then broken very small with a skimming dish, and allowed to settle down till all the whey be taken off; it must then be cut with a knife in a drainer, and allowed to remain in it till properly cooled.—The curd must then be put into a vessel, and cut very small with a curd-knife, and a small quantity of salt used; it is again put into the drainer a second time, and allowed to remain there for the space of an hour. It is again taken out of the drainer, put into a vessel, well washed, and the requisite quantity of salt added. It is then put into a cloth, then in the cheese vat, and lastly in the press, and the cloth removed thrice a day, until the curd is properly pressed into a cheese."

Mr. Dickey heats his night's milk, for full milk cheese, to a temperature equal to that coming from the cow in the morning, before he adds the rennet. Mrs. Lumsden sets her milk, i. e. puts in her rennet, when the milk is at a temperature of 85°.

BUTTER.

Mrs. Macinnis, who received a premium, describes her mode of making and curing butter, as follows:—

"Earthenware vessels are used for keeping the milk, and placed in the dairy on cool stone shelves. The milk allowed to stand twelve hours, after which the cream is taken off and put into earthen jars, and made into butter the following day. The butter, when made, clean washed with spring water, and half an ounce of fine salt given to every pound of 16 ounces. It is then kept wound up with a cloth, as it accumulates for four or five days, when it is all worked together, and another half ounce of salt added to every pound, and packed into the vessel that is to contain it, with a wooden mallet made for the purpose. A little salt is sprinkled over the top, which is covered closely up, so as to exclude the air as much as possible."

Mr. M'Kenzie's milk vessels are all made of oak; the dairy-house stands in an airy situation, into which no one is allowed to enter but the dairy-maid. The milk vessels are always scalded in hot water, or steamed, before they are used.

"Joseph Leisk makes butter from cream and milk, because he considers it only practicable in large dairies to make butter from cream alone. The milk is put into large vessels, and left undisturbed for four or five days, until churned. It is necessary that the milk be actually *soured*, not thickened, otherwise it will not part with all the butyraceous matter; but it should be soured by natural, and not by artificial means, by letting it stand a sufficient time. Two or more milkings may be churned together, provided they are not mixed but in the churn. It is necessary to add warm water, to raise the temperature to 90°, otherwise the butter will not all be extracted from it. The butter is first packed in stone dishes, and afterwards in wooden kegs. The second packing gives an uniform color and taste to the butter."

William Merriless begins to churn his cream at a temperature of 56°, when churning rises it to 60°. He does not wash his butter; but it is beaten with the hand till it is completely cleaned of the milk.—The quantity of milk produced from cows fed on artificial grasses is much greater than that from cows fed on the hill; but the quality of the latter is much superior to that of the former, and yields much more cream. One pound of fine salt is allowed to one stone of 14 lbs. of butter. The butter is laid aside for two days, when it is again broken down, and beaten with the hand, and packed into small jars for family use.

A Hint to Housewives.

As greatly as we commend scrubbing, as promotive of cleanliness and health—and loth as we are to check any tendency to tidiness in our wives and daughters, we do believe that scrubbing our floors with water is sometimes carried to a prejudicial length. Ventilation, or pure air, is the first requisite to health and comfort; and dry heat, though it be uncomfortable, is seldom unhealthy. But moist heat is the bane of health. When, therefore, the floors, or even the hearths, of our apartments, are subjected to a weekly or daily drenching, in order that they may look neat and cleanly, they must be unhealthy. Now a portion of this water is converted into vapor, in proportion to the temperature of the room; and unless ventilation be given to a dry external atmosphere, the inmates of the dwelling must suffer, in a measure, the evils that result from a marshy residence. One of the most eminent surgeons of London, the late Dr. Taunton, has declared, that many an illness had been caused, and frequently death ensued, from sleeping in a bed room that had been scoured, and had not been thoroughly dried, before its occupant retired to rest. The preventive of the evil, consists in scrubbing during the prevalence of a brisk dry atmosphere, when the windows of the rooms can be freely opened; or in using *clean dry, or hot sand, instead of water*—a practice which is coming into use with high prospects of usefulness. Combe has furnished us with a good illustration of the advantages of using sand, instead of water, for purifying inner apartments, in a letter which he has published from Capt. Murray, R. N. That gentleman commanded a ship of war, on the West-India station. While five other ships in company, lost from sixteen to fifty men each, not one of Capt. Murray's crew, consisting of 150 officers and men, and although moored in the midst of the squadron, and having daily intercourse with the other ships—not one of Capt. Murray's crew died or was sick. He ascribed this happy exemption to the circumstance of keeping his ship clean and *dry*. "*Every morning the lower deck, cock-pit and store-rooms were scrubbed with dry holystones and hot sand, until quite white*—the sand being carefully swept up and thrown overboard."

The admonition which this fact affords, may prove useful to the master, as well as to the mistress, and should instruct him to keep the grounds about his house and out buildings free from filth and stagnant water, and to avoid building in marshy situations, if he would avoid sickness himself, and prevent it in his family.

Forcing Rhubarb.

Mr. Knight has left directions for having this excellent plant in use for winter. He gives the following *rationale* of the principles on which his practice is founded. "The root of every perennial plant contains within itself, during winter, all the organizable matter, which it expends in the spring, in the formation of its first foliage and flower-stems, and it requires neither food nor light to enable it to protrude these, but simple heat and water; and if the root be removed entire, as soon as the leaf becomes lifeless, it will be found to vegetate, after being replanted, as strongly as it would have done if it had retained its first position." His mode of proceding was literally to fill some large deep pots with the roots taken from the garden, in autumn. Some fine sand loam was then washed in, to fill entirely the interstices between the roots, the tops of which were so placed as to be level with each other, and about one inch below the surface of the mould in the pots, which were covered with other pots of the same size inverted upon them: being then placed in a vinery, where there was no light, and copiously supplied with water, the plants vegetated rapidly and strongly, and from each pot he obtained three successive crops, the leaf-stocks being crowded so closely as nearly to touch each other, over the whole surface of the pots. The heat of a hot-bed, kitchen, and, on the approach of spring, a cellar, will afford a sufficient high temperature. Tubs or other wooden vessels may be substituted for earthen pots. Plants which have grown one year in a rich soil, either from cuttings or seeds, will answer to force.

"Serious Suggestions Addressed to the Interests and Honor of Farmers."

Such is the caption of a very able article, addressed to the farmers of Kentucky, by the editor of the Franklin Farmer. Its object is to demonstrate the propriety of a more liberal state policy for the improvement of its agriculture, particularly by the establishment of schools of practical and scientific instruction. The certain tendency and sure effect of such a policy, it is contended, will be, to enlarge and elevate the science, i. e. the principles and practice of husbandry; to promote vast improvement in the modes of tillage, and all the departments of husbandry; to contribute the most effctual aids, physical and intellectual, to this great branch of industry, and to elevate the dignity and standing, in every sense, of the tillers of the soil. Commerce and manufactures, which, he adds, are subordinate interests, have received ample—we do not say unmerited—encouragement, while agriculture has been wholly neglected. And why, he asks, is this? It has been owing, he intimates, to the listlessness and indifference of the farmers themselves. He closes with the following appeal to their interests and patriotism:

"Now we ask the farmers of Kentucky, each and all; have you done your duty to yourselves, to your sons and to your country, in regard to the great measures in which you are most deeply interested? Have you done enough for the promotion of agricultural education—have you felt and *acted* as if you felt, that your pursuits are the most important and dignified of all that engage the labors of mankind? Have you been willing, or at least, inactive spectators, of the course of legislation, which has passed by the interests of agriculture, unnoticed? Have you stood by and witnessed acts of favor extended to every other pursuit, and your own neglected as if unworthy of attention? Have you ever, as a freeman of this republic, and having the right to instruct your representatives, urged them to support measures of legislation in favor of agriculture; or rebuked or reprimanded them for their disobedience? Have you done nothing for the encouragement of agricultural education? Have you never felt, that in your pursuits as a farmer, in your actions as a citizen of the country, in your discipline as a father;—that you owe a great moral debt to your contemporaries, to your country and to your children, which cannot be discharged but by engaging heartily and earnestly, with all your ability and energy, in the labors which we have suggested? If you return a negative response to these inquiries, you have failed to sustain the high dignity and character of your position in community. You have met, as meets a coward, the noble responsibilities imposed on you by your existence in the nineteenth century, in this age of onward and upward march to the highest point of prosperity and improvement in all that relates to the happiness and well being of your fellows. You have, in short, sunk below the standard which the age has excited for the measure of your standing in community. But notwithstanding this dark picture, there is a day of brightness dawning, whose light will allure to press you onward in the paths of national and individual prosperity and honor. You cannot longer remain in the rear. Your post is in advance; and you must occupy it. The age expects you to transmit to your sons, such an amount of useful, practical knowledge, and withal, such a spirit of pride in your pursuits, as will testify that you appreciate the value of one to the success of the other; and such as will render your sons honorable and useful members of community. You are to demonstrate, in short, by every means and in every action, that your character and pursuits are the most exalted and dignified, and that you *know* it, and appreciate your position rightly. With these remarks we leave you for the present to the responsiblity you owe yourselves, your children, your country and your God."

The example of Massachusetts, in encouraging the improvement of agriculture, we hope at least will arrest the inquiry of all Legislators, as to its tendency upon the interests of the State, if it does not induce them to imitate it. The state agricultural society of that state has offered premiums to exceed $2000, and six of her county societies give each over $600. These premiums have been awarded for several years principally through the wisdom and liberality of her legislature; and no one murmurs—all classes are pleased, because all classes, either directly or indirectly, participate in its benefits.

On the Practicability and Means of Improving our Agriculture.

An Address, delivered before the Fulton County Agricultural Society, on the occasion of its organization, at Johnstown, Oct. 18, 1838, *by* J. Buel; *published at the request of the Society.*

Gentlemen of the Society—To those who can carry back their recollections thirty or forty years, the improvements which in that time have been made in the mechanic and manufacturing arts will appear surprising. Forty years ago we imported all our cotton, and most of our woollen goods, except of household manufacture—all of our hardware and cutlery, a great portion of our nails, saddlery, hats, &c. and I well remember, that a hatter in Albany, to give currency to his hats, was obliged to deceive his customers, by putting into them bills, representing them to be of British fabric. Now most of these, and many other articles indispensable to our comfort, are not only produced within ourselves, in quantities sufficient for domestic use, but millions in value of them are annually exported to foreign countries. Not only are they produced in abundance, but they are produced at a far less price than formerly. East India hum-hums, a coarse slazy kind of cotton goods, were once reputed cheap at twenty-five cents a yard. We have now better goods, made at our mills, at six and seven cents a yard; and it is but little more than twenty years, since the invention of power-looms reduced the price of weaving from eleven and twelve to one and two cents a yard. There is scarcely a manufactured article in use, which has not, in consequence of the improvements in mechanics and manufactures, been improved in quality, and diminished in price.

Whence these great and recent improvements in our sister arts? They are not owing to the diminished price of labor; for that has increased, rather than diminished; nor to a reduction in the price of provisions—for these, too, are higher than formerly. They have been brought about by the diffusion of useful knowledge, and the consequent development of the powers of the mind. The manipulations in the arts have been greatly abridged by labor-saving machinery, and many of the processes have been simplified and cheapened, and the results rendered certain, by the aid of science—by a knowledge of those laws which Providence has ordained for the government of matter, inorganic, as well as organic. Mind has been put in requisition, as well as physical power. And these changes have in some measure been effected by a more systematic arrangement of business—by a division of labor—and by a general and rapid dissemination, by means of the press, of a knowledge of the improvements which are every day being made in these useful arts of labor.

Let us now turn to agriculture, the parent of all arts—the source of our purest and most substantial enjoyments—the basis of our national prosperity and independence. This is as susceptible of improvement as the other arts of labor. What progress in its improvement have we made, during the last forty years? Have our labors been abridged by the general introduction of improved labor saving implements of husbandry? Have our lands increased in fertility, and in the amount of their products? Has the diffusion of useful knowledge, in the business of husbandry, been as extensive as it has in the manufacturing and mechanic arts? The valley of the Mohawk was long ago celebrated for its fertility and its wealth. Have enterprise, intelligence and improvement, in rural affairs, kept pace with the spirit of the age? I fear these questions cannot be answered affirmatively. I fear that it will be found, on an impartial investigation, that while all the other arts of labor have, with rapid strides, been progressing in improvement, our farmers have too generally been taking a Rip Van Winkle nap;—that with all the natural means of improvement, and all the common incentives to employ them, they have been listlessly treading in the footsteps of their fathers, unmindful of the salutary changes which are enlightening and enriching those engaged in other branches of labor.

I have said that agriculture is susceptible of improvement, and that our farmers have the power and incentives to bring it about, if they would do as others do, make a joint stock of their knowledge, and thus individually profit by the experience of all. Scotland, in a little more than forty years, has increased her agricultural products four fold, and yet but few of her farmers are owners of the land they till. They are tenants at a heavy rent, which Prof. Low, one of her late agricultural writers, averages at more than eight dollars an acre per annum, while the burdens, in the form of taxes, are assumed by him to be about $140 upon a farm of 500 acres. Thus the occupant of such a farm pays annually, in rent and taxes, about 4,500 dollars, which of course is a draw-back upon his nett profits, and most of which the American farmer, with Scottish intelligence and industry, might annually add to his income. Yet the Scotch farmer prospers under all these disadvantages.

What I have remarked of the increased profits of Scotch agriculture, will apply with very little abatement, to many districts of our country, and particularly to the county of Dutchess, in our state. Entire farms in that county have netted the cultivators an annual profit of fifteen and seventeen dollars an acre. Forty years ago these farms did not probably nett a quarter of this sum; and if I am able correctly to identify one to which I make reference, it was, forty years ago, mostly *old field*, a term denoting worn out land, and was lying in commons!

One of the best farmers of the age, a man of science and extensive practical knowledge in farming, has affirmed, that by doubling the expense, in labor and manure, he has, upon the same land, been enabled to treble his profits, and to quadruple his products. I allude to Von Thaer, who has for twenty-four years been at the head of the great agricultural school in Prussia.

If I might be permitted, without being charged with egotism, to cite my own experience in the business of improvement, I would point to my farm, on the Albany barrens, which many of my hearers have seen, I presume, in its present and former state—as a further evidence that we *can* improve our lands. Twenty years ago, my soil was poor,—very poor—and my farm a part of the commons—a waste. It is now as productive, and its culture affords as liberal a profit, as any of the lands in yonder fertile valley. It is worth, for farm culture, the interest of two hundred dollars per acre; and this year the product has been greater than I have named, although but ordinary labor was bestowed in the culture. It may be said that I have expended capital in my improvements. This is true. I laid out extra money and labor to put it into good condition, and I am now realizing compound interest upon the amount of the outlay: For having *put it* into good condition, I am enabled to *keep it so*, and to cultivate it, with as little expense as I could cultivate poor lands that would not yield me a third of the profit that I now realize. Capital is useful to its owner in proportion to the income which it brings him; and if by vesting it in farm improvements, it is made to yield as much as it would yield in bank stock, or loaned on bond and mortgage, it would seem to be prudent, if not wise, so to vest it.

I believe it will not be denied, by any one conversant with the history of the times, that improvements in *our* agriculture have been trivial, compared with those which have been made in the other arts of labor, or those which have been made in husbandry in other districts and in some other countries. On the contrary, it is but too apparent, that, with individual and local exceptions, our old lands have been deteriorating in fertility without any material improvement in the mode of their culture. A bare reference to the wheat crop in the valley of the Mohawk, comparing it now with what it was forty years ago, will serve to substantiate this truth.

From the examples I have cited, and from the personal observation which most of you have been enabled to make, I think it will readily be admitted, that we are capable of greatly improving our farming operations, and of thereby adding to our wealth, our comforts, and to the substantial prosperity of our country. If by means of new farming implements—the improvement of our domestic animals—and a better system of culture—the labor which now netts us fifty dollars, can be made to nett us one hundred dollars—which I consider within the range of probabilities—we may then double both our products and our profits; and, under the guidance of correct principles, double, too, our usefulness to society.

The progress of improvement in husbandry, will be graduated, in a measure, by the degree of intelligence which directs its labors. "It appears to be strange—and yet we see it to be true"—says the Rev. C. Young, "that the more ignorant a man is, the more obstinately is he wedded to his own notions and ways—the more ready to scoff at and oppose every thing that is new. Self-conceit and prejudice, the greatest foes to improvement, are the legitimate offspring of ignorance. And in proportion to the degree of ignorance, in a community, will be the hostility to improvement, and the derision, and even persecution, at which all attempts at innovation and reform will be met. The spirit of improvement is thus cowed, and even smothered. And if occasionally, a bold genius struggles into life, and exhibits his inventive powers, he hazards his peace—sometimes even his life. When Hargrave, less than a century ago, attempted to introduce the spinning-jenny, which he had invented, into the cotton manufacture, he was obliged to fly from Lancashire in England, where he lived, at the risk of his life. The first saw-mill ever erected in England was destroyed by a mob, because they thought it would take bread from the families of the sawyers." Fortunately in our day and country, acts of violence towards innovators upon old modes of farming are not to be apprehended. We can only complain of a listless indifference to improvement, and of a conceited ignorance, which rejects the useful, because it is new.

If our neighbor discovers on his farm a valuable mineral, and works it to great profit—we commend him for his good fortune. If the like mineral abounds on our own farms, and we can work it to equal advantage, what course, as prudent men, ought we to pursue? Should we not deem the man highly reprehensible, who neglected such an opportunity of adding to his wealth, by adopting the example of his fortunate neighbor? Now what are our farms but mines of wealth, if rightly improved? They are certainly so to many cultivators; and if we will follow their example in working the mine, and in husbanding the wealth which it yields, our farms will be such to us. If we lack the knowledge which precedes improvement, let us seek for it, by observation, by study, and a mutual interchange of opinions and information, with our brother farmers in associations like the one I am addressing. We shall see and hear, at these meetings, much that is new,—much that is instructing and useful, and much to stimulate us to new exertions in our business.

Again—if a man embarks in a speculating business, and prospers in it, how ready are his neighbors to become his rivals and competitors? Good farming is a speculation—with almost a certainty of gain—without the probability of loss. In agriculture, besides, competition excites no unkind feelings, as it is apt to do in other employments, or should not, for the improvements of every competitor may prove beneficial to all. What one makes does not lessen his neighbors' profits; but, on the contrary, has a tendency to better the condition of all around him. There is no monopoly in good farming.

The propensity which has too much prevailed of late years, to quit farming for a more lucrative, a more genteel, or a less laborious employment, has been a great obstacle to agricultural improvement, and has tended much to lower the respectability of our yeomanry in the public estimation. How many farmers have we seen, who were doing well upon their farms, allured by a weak ambition, into some untried business, in which they had every thing to learn—how many such, I say, have we seen bankrupted in fortune, and not unfrequently in reputation. There is a vast difference in the chance of a man's improving in the business to which he has been brought up, and his succeeding in a new one, of which he knows little or nothing. In the one case he has a capital in his experience; in the other, he enters into competition, without this capital, with those who are far his seniors in skill and in practice. A farmer may *improve* in his *old* business, at much less risk, and with less trouble, than he can *learn* a *new* one. He mistakes equally his interest and his happiness, therefore, who quits his farm, or neglects to improve it, upon the untried experiment of doing better elsewhere. There is no employment which promises a greater portion of health and independence, the main sources of our enjoyment, than that of agriculture; while the return it makes, to skill and industry, is as bountiful, probably, as is useful to ourselves, our families or our country.

The first step to improvement, is to acquire better knowledge in our business;—the second, to apply this knowledge to the management of our farms. He that is conscious he *can* improve, and resolves that he *will* improve, will most surely succeed—and the means of improving will readily present themselves to his mind. Agricultural journals will afford him a ready and cheap means of instruction. They chronicle and bring to him, periodically, at trifling expense, the improvements that are continually being made in the business by which he lives, and expects to acquire wealth for himself and his children. They convey to him all the discoveries in the science, and improvements in the art of agriculture, which are made in Europe or America, and that are calculated to improve him in his business, and advance his condition in life. They explain to him the principles upon which the new system of husbandry is more productive, more certain, and more profitable, than the old system; and they demonstrate the correctness of these principles by the successful results they give in practice. They explain to him the operation of manures—as essential to the growth and perfection of his crops, as hay, grain and pasture are to the growth and productiveness of his cattle—and enlighten him in the means of augmenting, and of applying them in the most economical manner. They bring to his knowledge every improvement and invention in the labor saving implements of the farm. They instruct him in the principles and most approved modes of draining—and of rendering salubrious and productive, those portions of his farm which have hitherto, perhaps, been a prolific source of disease and death to his family, and neighborhood—a highly useful branch of modern improvement in husbandry, which we have yet to learn. They demonstrate to him, in principle, and by numerous illustrations in practice, the utility of alternating crops, and instruct him in the economy and management of root culture. They treat of the comparative value of different breeds of farm stock, and furnish the best examples of profitable management. They teach useful lessons in gardening and orcharding, and designate the fruits, roots and garden productions most useful to the family, and most profitable for market. They abound in instructions in household economy, and show, that under judicious management, the garden and the farm may be made to produce most of the necessaries, and many of the elegancies and luxuries of life. They are in fact a sort of agricultural museum, in which all that is new—all that is useful in farming—may be found, and applied to the individual benefit of the reader. They are, in effect, a sort of universal agricultural society, which collects into a focus, and from thence diffuses over the land, a knowledge of all that is useful in the improvement of the soil. But independent of these, and other advantages I might particularize, agricultural journals are worth thrice their cost to the children of the family, in inducing in them a taste for useful knowledge, and a desire to improve their minds, their manners and their morals. The good seed, sown in the spring time of life, will produce its fifty and its hundred fold, in the summer of manhood.

Another and very important means of improvement is agricultural societies or associations. Although these have been of long standing in Europe, and have contributed largely to agricultural improvement there, more new ones have been formed in the United States, in the last five or ten years, than ever existed with us before. They afford a strong indication that the important business of husbandry is commanding, as it ought, the particular attention of the American people; and that the benefits resulting from these associations have become palpable and important. Agricultural societies tend to bring under the eye, or to the understanding, of each member, and in a great degree to the public at large, the best household and farm products, and the best agricultural practices, of the country or district in which they are established, and thus enable each individual to appropriate to his own use, the experience and the improvements of his neighbors. The example of every good farmer produces a beneficial influence upon those around him; who seeing his approved modes of management, and the advantages resulting from them, will not fail ultimately to adopt them. Hence the more good farmers there are, the greater will be the ratio of general improvement, and consequently of public benefit—for it is the earnings and products of agricultural labor, that mainly contributes to the prosperity of the other classes of society, and to augment the aggregation of the national wealth. When the harvest is short, every department of business feels the electric shock. When it is abundant, a new and happy impulse is given to every sort of business. These considerations show, that it is the interest alike of all, to patronize and encourage every effort that is made to increase the products of the soil. One of the oldest societies in our country is that of Berkshire, in Massachusetts. I have occasionally attended their exhibitions, traversed the county, and marked its improvements in husbandry, during the last twenty years; and I feel a perfect conviction in my mind, that the county has been benefitted twenty dollars for every dollar expended in premiums, in a pecuniary point of view. But it is not the rapid improvement of the soil alone which has resulted from the establishment of her agricultural society—the improvements of the mind have kept pace with, or rather preceded, the improvements in her husbandry. That county has probably the best schools in the country; and the general intelligence of her population ranks high.

Among other benefits likely to result from the establishment of agricultural societies, Mr. Anderson, in a late address, before the society, at Danville, Ky. enumerates the following.

"They will elevate the character of the farming and agricultural class of society. They will increase their general intelligence, their aggregate wealth, and give them, as they deserve to have, a control over the morals and politics of society.

"They will increase the national wealth.

"They will be not only calculated to elevate the character of agriculture, but the standard and spirit of education; for as men increase in knowledge even of a useful character, aspirations to a higher standard in every thing else, are enkindled.

"They will furnish essential aid to the legislature of a state.

"They will greatly increase live stock, in purity of blood and quality.

"They will increase labor saving modes of cultivation, as well as labor saving machines."

As intimately connected with the improvement of husbandry, which this society is specially formed to promote, permit me earnestly to recommend an early attention to the establishment of Common School Libraries. The improvement of the mind must precede the improvement of the soil. Physical power belongs to the brute, as well as to man; but the application of intellect to aid and control this power, is the peculiar prerogative of man; and it requires no argument of mine to show, that intellect is efficient and potent, in husbandry, as it is in the other business concerns of life, in proportion as it is brought under good culture;—that a well cultivated mind, like a well cultivated soil, can be rendered far more productive in usefulness, than one that has not received the advantages of culture. Common School Libraries will not only be useful in the particular business of farming, but in all the relations in life in which we or our children may be called upon to perform a part. All the gradations in society, from savage life, to the highest state of civilization and refinement, have principally been owing to the greater or less cultivation of the human intellect. Useful reading not only confers postive benefit, by the instruction and admonition which it imparts, but it often averts positive evil, by keeping us from loose or bad company, and thereby preventing the formation of idle or bad habits. The youth who finds pleasure in reading, and has the opportunity of storing his mind with useful knowledge, will seldom be driven to the haunts of vice and dissipation, to indulge his grosser appetites. And the mind too, like the soil, will grow weeds and briers, thistles and thorns—if not made, by good culture, to produce that which is comely and useful. The liberal appropriation by the legistature, for the establishment of Common School Libraries, if seconded, as I trust it will be, by the public at large, will form a new and auspicious era in our history, and contribute essentially to render us, what we ought to be—a more intelligent and virtuous—that we may longer reman a free and independent—people.

The judicious cultivation of the soil is now deemed so essential to national prosperity, that it has become the settled policy of the most enlightened governments, to take a direct and efficient interest in the improvement of its agriculture. Schools of scientific and practical agriculture, in which youth are taught the best modes of practice, and instructed in the principles upon which that practice is based, are continually multiplying under governmental patronage on the old continent. National societies have been established for rewarding those who benefit the state by their improvements and discoveries in husbandry, and for diffusing the useful information which is thus brought to a common centre—and the rewards as well as the services of those who are thus engaged in promoting the common weal, are in most cases paid from the public treasury. Prussia has wisely engrafted instruction in agriculture upon her system of common school education; and even in what we have hitherto considered the benighted regions of Prussia, and among the oppressed of Ireland, we see evidences of wisdom, and the dawn of a brighter day, in the establishment of agricultural schools. Our sister state, Massachusetts, has been foremost among us to adopt a liberal and enlightened policy toward this her primary branch of industry. She has disbursed large sums from her state treasury, annually, to sustain and encourage county agricultural societies; and when the law making these appropriations, was about to expire, by its own limitation, so well satisfied was her legislature, of its utility, that the law was renewed with great unanimity. That state has also provided for an agricultural survey of her territory, which has been two years in progress, with a view of bringing before her whole agricultural population all that is found excellent in the business of her farming population. How far New-York will profit by these examples of usefulness—or when she will begin to imitate them, will depend very much upon her farming population. What they *demand* will be granted. But little need be expected for the promotion of agricultural improvement from our public councils, while the farmers themselves generally manifest a reprehensible indifference in the matter.

In the brief remarks I have made, I have endeavored to show the practicability of improving our agriculture, and of thereby raising the character of our agricultural population; and have suggested some of the means by which the desired improvement may be brought about. I have already trespassed too far upon your patience, I fear, to go into any of the details of improved husbandry. Let it suffice to say, that they embrace a better economy, and more general application of manures—a system of thorough draining—the introduction of improved labor saving machines and implements—the improvement of farm stock—the exclusion of impure seeds—the extension of root culture—the alternation of crops where practicable—the improvement of our common roads—the introduction of system into all the departments of farm and household labor—the cultivation of *as much land as can be cultivated* WELL—and the keeping of *as much farm stock as can be profitably fed and fattened*—AND NO MORE. All those improvements *have been made*, and *are making*, elsewhere. They *can* be made here; they *will be made here*, by the intelligence, the enterprise, and the laudable competition, which this society will diffuse and call into action, if its labors are judiciously persevered in.

I am happy to recognize, gentlemen, in the formation of this association, a disposition in its members to aid in the work of agricultural inprovement. The object is a worthy one, because it aims to enlarge the means of human sustenance and the measure of human enjoyment; and by encouraging and honoring industry, tends to advance the moral character and substantial prosperity of the country. I hope you may prosper in these public spirited efforts, and that FULTON county, may become as distinguished in the annals of agricultural improvement, as the individual whose name it bears, is already renowned in the history of steam navigation.

Notices to Correspondents.

MADDER. W. R. of Gloucester county, N. J. will find the information he asks for, in regard to the cultivation of madder, at pages 35 and 141, vol. I—at pages 20 and 171, of vol. II—and at pages 72 and 189 of vol. III. It would be an unpleasant repetition, to most of our readers, to republish these directions.

LIME AND MARL. A correspondent at Washington, D. C. writes as follows:—"The application of lime and marl, in Maryland and Virginia is producing wonderful results. I have no doubt, that in a few years, all our worn out exhausted lands, will rank among the most productive in any part of the United States, by the judicious application of those two valuable calcareous manures, or rather agents in agricultural improvement. I am engaged in applying lime to a small exhausted farm near this city. So far the effects are great. So far as I shall have a full and fair experiment of the results, I will make them known in detail, through the columns of the Cultivator, if they shall be deemed worthy of insertion. I am making the experiment, whether lime applied on poor exhausted land, in very small quantities, unassisted by manure, will *alone* recover the land, except that taken from swamps, or in other words, rich rotted vegetable matters. I try the lime alone also. What is your opinion on this point?" Our opinion is, that lime must have vegetable or organic matter to work upon, to restore fertility to the soil. If our recollection is right, the soil about Washington is a tenacious red clay, so hard, when dry, as to prevent the plumules of tender plants penetrating it freely. Lime will unquestionably improve its mechanical texture; and if brought in contact with inert vegetable matter, whether already in the soil, or brought thither from swamps, it will improve its fertility, in proportion to the vegetable matter which the lime may render soluble, and thus transform into vegetable nutriment.

PEAT SWAMPS. Willard Earl, of Hubbardston, Mass. will find as ample directions as we can give, for reclaiming peat swamps, at pages 157, 174 and 190 of our last volume. The first thing is thoroughly to drain them, so that water will not stand and stagnate within the natural range of the roots of farm crops. The second requisite is, to induce a decomposition of the vegetable matter, by paring and burning, by the application of lime or unfermented manures, or by a liberal admixture of earthy matters. The third is, to till and subdue the upper stratum till it is fit to lay down in meadow. The fourth is, if it is to be kept in meadow, to give it a top-dressing, once in three or four years, with manure, compost, ashes, lime or marl. We have yet much to learn in draining. We do not go deep enough; and we have yet to learn from experience, that under-draining, except upon the main outlets, is far the most efficient and economical.

MARL. Theodore Allen, of Hyde-Park, Dutchess, writes us, that he has just opened a bed, extending over several acres, and lying within twenty rods of the Hudson, of what he believes to be *shell marl*, and has sent us a sample of it. Without having subjected it to an accurate analysis, we venture to assure Mr. Allen, that the specimen *is* shell marl, of superior quality, and that in his "several acres" he has a source of great fertility and profit.

PUMPKIN, SQUASH, &c. A correspondent inquires of us where the seven years, and mammoth pumpkins originated, what are their qualities, &c. We cannot answer either of these questions. We have grown both, but have thought so little of their quality, from their appearance, that we have not had any of them cooked. Another equally puzzling question has been asked us, viz. what is the distinction between a squash and a pumpkin?

The pumpkin, squash, water-melon, gourd, and we believe what is termed the vegetable marrow, belong to the same class, or family of plants (*Cucurbita*); and although there are but six species described by botanists as belonging to this class, there are innumerable varieties, partaking of the qualities of two or more species. The species named by Eaton, are, the egg squash, club squash, flat squash, pumpkin, water-melon and gourd. Instead of giving three species of the squash, Loudon gives three of the gourd, and one of the squash. All the varieties of pumpkins, squashes, water-melons and gourds have sprung from a mixture of these six species; and but few of the varieties held by us in the highest estimation answer the description in fruit, given in books—so remarkably have the varieties multiplied, and in many cases improved, by cross impregnation. We have apparently six varieties now growing in our garden, from seed which we planted as the apple bush squash—in consequence, we presume of the parent having been grown along side of other varieties and species. The pumpkin is cultivated in England as a curiosity; yet, says Loudon, some of the inhabitants grow it on dunghills, and "when ripe, they cut a hole in one side, and having taken out the seeds, fill the void space with sliced apples, adding a little sugar and spice, and then having baked the whole, eat it with butter." Poor souls! not to know the luxury of pumpkin-pie!

The vegetable marrow, being of recent introduction, having been first obtained but a few years since from Persia, and being withal an excellent species, we will copy its description from Sabine, and his directions for preparing it for the table.

"The fruit is of a uniform pale yellow, or light sulphur colour; when full grown it is about nine inches in length, four inches in diameter, and of an eliptic shape, the surface being rendered slightly uneven by irregular longitudinal ribs, the terminations uniting, form a projecting apex at the end of the fruit, which is very unusual in this tribe. It is useful for culinary purposes in every stage of its growth; when very young, it is good if fried with butter; when large, or about half grown, it is excellent either when plain, boiled, or stewed with rich sauce; for either of these purposes it should be cut in slices. The flesh has a peculiar tenderness and softness, from which circumstance it has, I suppose, received its name, much resembling the buttery quality of the *beurre pears*, and this property remains with it till it is full grown, when it is used for pies. It is, however, in its intermediate state of growth, that I consider it likely to be most approved. Compared with all the other kinds which I had growing, its superiority was decided. I consider the vegetable marrow without a rival."

We have grown the true vegetable marrow two seasons; and although we have not used it in the intermediate state of its growth, as recommended by Mr. Sabine, we esteem it among the best varieties of the cucurbita for boiling and for pies. It is cultivated like the common pumpkin or squash, and will ripen in a high latitude.

INDIAN CORN IN ENGLAND. We are asked by a Kanawha, Va. correspondent, if Indian corn is grown in England? It is *not* grown there as a *crop*, but occasionally as a *curiosity*. Loudon says, it *may* be cultivated in very warm, dry situations, if the dwarf red grained be adopted. Cobbett did grow and ripen some; but no attempt, we believe, has been made to profit by his lessons, farther than to raise a few hills for the table, while green.

Will ruta baga do as well on stock ground as on sod? is a question addressed to us by D. J. Bent, of Chester, Pa. We think it will, if the former is made as rich as the latter, including the fertilizing matter of the sod. A sod is beneficial in two ways: it affords the food of plants, and it tends, if left carefully turned, to mitigate the effects of drought. The decomposition of vegetable matter, excluded from the atmosphere, not only *preserves*, but *produces*, moisture. Mr. Bent also asks—will manure, applied in an unfermented state to corn, in the spring, benefit a succeeding wheat crop, as much as it will if permitted to rot in the yard, and applied after the corn is harvested? We answer *it will, and more.*

It loses less by fermentation in the soil than it does in the yard, and it is better commingled with the soil by the culture of the corn, than it would be by the mere preparation for the wheat-crop.

CORRESPONDENCE.

Plan of a Barn.

Near Brownsville, Pa. Nov. 1, 1838.

Hon. J. Buel—As the important subject of barn building has awakened the attention of the farming community, I would place at your disposal the plan of a barn I have just erected. It is the plan most usually adopted by the Germans of western Penn. The cost is about eleven hundred dollars; and for extent of accommodations, for grain and stock, for durability, for convenience and not being liable to get out of repair, it has few superiors. Bank barns have many advantages over those erected on level ground, and surrounded with sheds,—the manure is collected in front, in one place, and all other sides are kept clean; the stock is more easily fed, on account of the fodder being nearer to the place where it is wanted, and much less roofing is required for the same purpose. This barn is ninety-five feet long, forty-four in width, including an overjet of eight feet: height of main frame sixteen feet, and of the overjet twelve; that is, above the wall.

[Fig. No. 61.]

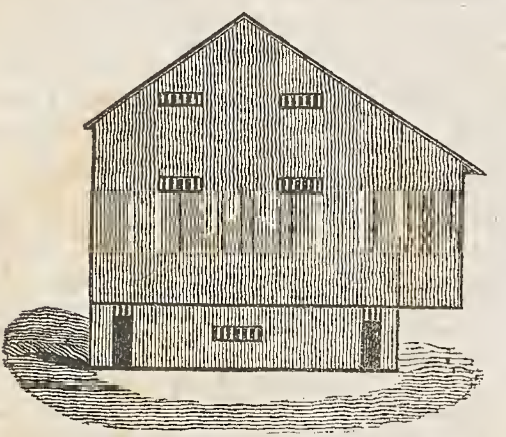

Fig. 61, represents the end view. Several lattice windows are preferred, so as to let off the rarified, moist and heated air in small bodies; for a current of this air is known to be one of the best conductors of electricity; of course then, means should be taken to prevent its passing off in one dense volume; free ventilation would seem to answer this purpose. Is not the neglect of this precaution the cause of so many barns being burned by lightning? the whole current passing out of one opening?

[Fig. No. 62.]

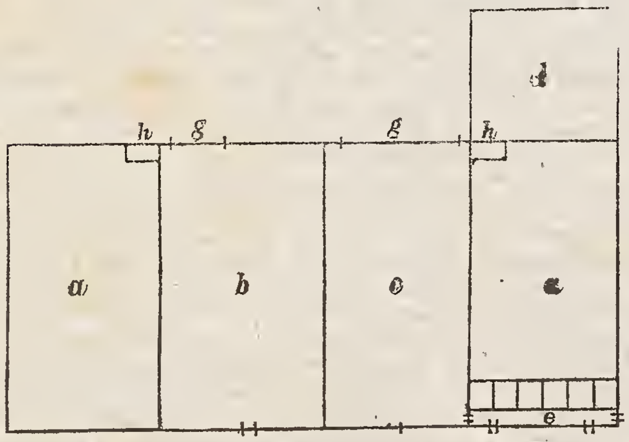

Fig. 62, represents the second story; (xa and a) represent hay or grain mows; (b) a mow with large doors (g), and strong floor, into which a wagon can drive so as to fill the mow (a); after which the mow (b) may be filled from the threshing floor (c); so that no space in the whole extent may be left unoccupied, except the threshing floor; and after the mow (b) is freed from its grain, it also serves for a threshing floor for the mow (a). The mow (a), however, is intended for hay, which even then leaves space enough for all the grain of farms of the usual size; (e) is a granary, from which grain may be let down into a wagon, from a door in the end of the barn; (d) is a building for a stationary horse power of a threshing machine, which I intend erecting; (g g) are barn doors; (h) stair and gangways to throw hay and straw into the stable below. A straw house on the lower side with racks underneath, will be found very convenient, especially where much straw is threshed at one time. Joists are placed above the threshing floor on which to store away grain.

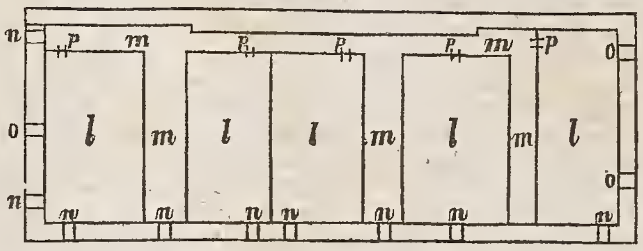
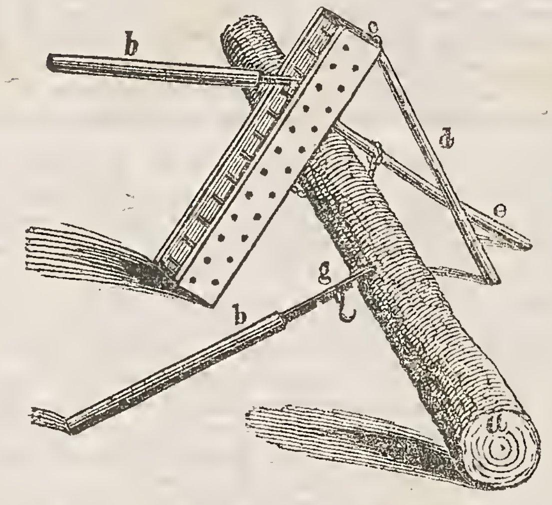
Fig. 63, is a ground plan of the basement story; (m) are passages the whole length of the building, and between the stables, from which the stock is fed; (n) passage and stable doors; (o) windows, which together with lath doors, and the space up to the sills above the doors being left open, serve to ventilate the stables sufficiently; (p) doors from passages into stables; (l) which will accommodate comfortably twelve horses, twenty-four cows or cattle, and twelve calves. The basement is mason work. I am thus minute, for in minutiæ consists convenience.

[Fig. No. 63.]



A Machine for Hoisting Logs.

[Fig. No. 64.]



I will also attempt to describe a machine for raising logs upon a wagon, with which a man and boy to move the pins, can load a log in five minutes, which it would require five men at least half an hour; (a) is the log, (b) a lever, the handle being wood, the part (g) on which the strength lies, of iron; on which iron part, is fixed a link and hook; (c) is two pieces of plank about seven feet long, eight inches broad, and one and a half thick, pinned side by side,—but wide enough apart to admit the lever and hook working easily between them,—bored with holes at regular distances on each side, so that as the lever is raised and lowered, the pins which go through the holes, and on which the lever rests, may be moved to the holes immediately above; the hook on which the weight lies, works between the two pins; (e) is a stick, one end on the ground, the other on the log; on which latter end is fastened a log chain extending under the log, and fastened on the hook of the lever; (d) is a prop to keep the machine from falling in the direction of the log. It works on much the same principle as the beam cider press. If you understand the principle, please explain it in a more intelligible manner, if it is deemed worthy of a corner of your valuable journal.

G. E. H.

Improved Wind-Mill.

Mr. J. Buel—Sir—I wish through the columns of the Cultivator, to bring to the notice of the public an important improvement in the wind-mill, made by Mr. Israel Keyes of Putney, Vermont, and patented by the United States. It is believed that by the aid of this improvement, wind power may be successfully used in all those places where water power is wanting.

The wheel used by Mr. Keyes, is a perpendicular wheel moving horizontally. There is a perpendicular shaft, with two setts of horizontal arms, to which are attached boards perpendicularly, which make the floats on which the wind operates. This wheel is enclosed in a circle of slats standing perpendicularly, and turn on a pivot at the bottom. Each slat laps on the edge of the one next to it, so that the circle is easily moved; and opens and shuts in the manner of moveable window blinds. In whatever direction the wind may blow, it operates upon one-half of the wheel, while it is turned from the other half: and when the wind is too violent, the slats are partially or wholly closed, as the case may require, by the operation of the machinery; so that the operation of the wind on the wheel, can be regulated as water is by the opening and shutting of the gate.

It is believed that this wind-mill may be successfully used for grist-mills, saw-mills, for mechanic shops, for grinding bark in tanneries, for the various purposes of farm use, as grinding provender, sawing wood, cutting straw, turning, or a churn, and for pumping water.

Mr. Keyes has erected for me a wind-mill, with a four feet wheel, to carry a pump of one and an eighth inches caliber; and the experiment has been entirely successful. It has much more power than is needed for so small a pump, in a well of common depth.

It heaves three quarts of water in a minute, and with a larger pump would probably heave two gallons in a minute.

This pump can be fitted up at a moderate expense, and cannot fail to be a valuable acquisition to those farms that are destitute of streams and living fountains.

This improved wind-mill has many advantages over those of the old construction, as will be obvious by inspection. It is cheaper built, in a more convenient form, has much less friction, more power, and is perfectly managable in a high wind.

E. D. ANDREWS.

Pittsford, Monroe co. Nov. 12, 1835.

A model of this wind-mill has been submitted to our inspection; and we are inclined to think favorably of it; though we cannot venture to give a definitive opinion of its merits till we have seen it thoroughly tried.—*Cond. Cult.*

Cultivation and Profits of Cucumbers.

Narrows, L. I. October 26, 1838.

Mr. Buel—Agreeable to promise, I will now endeavor to describe the manner in which cucumbers are cultivated on Long-Island, for the supply of the New-York markets, and will also give the produce and amount of sales from my crop of the preceding four years. Before proceeding with the matter, I would state, that the description is intended for field culture, and that our great object is, to have good fruit, and as early as it is possible to produce it, for two or three days makes a great difference in its value in the markets.

Cucumbers will grow on any good soil, but to have them early, we require a rich sandy one, of a dark colour, yellow and light coloured ones being later.—The field, if possible, requires to be protected from the south and northwest winds, and be situated near the bay or river, where there is always less danger from late frosts. The south winds with us, in May and June, retard vegetation more than any other, in consequence of their being chilly and cool, which qualities they receive from the ocean.

Ground intended for cucumbers, we prefer ploughing in August or the beginning of September of the preceding year, and sowing with rye; the pasture which this produces pays for the labor, and among its advantages are, the prevention of weeds going to seed and troubling us in the spring; the soil not blowing about in winter, especially on the knolls; neither is it so liable to blow when ploughed in the spring, in consequence of the roots of the plants, and the sustenance afforded to the crop by the decay of the rye. Previous to ploughing for the crop, there should be spread about seven two-horse loads of street or horse manure to the acre; but if the soil is poor, more will be necessary, and the ploughing should take place immediately after the spreading. The ground is then harrowed over two or three times, until it is mellow, furrowed shallow, with a plough, into hills four and a half feet asunder, manured with half a shovel full in a hill, which is flattened down with a hoe and covered about an inch thick with fine soil. Short hog manure, carted out of the pen the preceding fall, and cut over early in the spring once or twice, and made fine, is preferred for the hills; but this not being generally sufficiently abundant, we procure the manure of cows which have been fed on distillers' slops, mixed with that of horses, so as to make it sufficiently firm to handle with a fork, from New-York in the fall, which we mix with the hog manure. The manure should be cool, for fermentation in the hills is injurious to the plants.

The sooner the seed is planted after ploughing, the better: the time of planting depends upon the forwardness of the season, and it is generally commenced when single apricot blossoms are open, but some seasons earlier. About a week is occupied in putting in the first seed, and nearly the same period in planting over the first and second times. The casualties to which the seed and plants are subject, induces us to continue putting in seed almost every day for this space of time, so as to make certain work. It sometimes happens, when the weather has been unfavorable, that every hill in some fields is planted over the third, and even single hills the fourth time. I prefer spreading the first seed in the south half of the hills, the first planting over in the northwest, and the second in the northeast quarters: if it becomes necessary to plant over the third time, I put the seed in the south half, where the first seed by that time is rotten. If this plan is properly followed, the different plantings will not interfere with each other. We generally put in from thirty to forty seeds each time, and cover them with fine soil from three-quarters to an inch deep. Sprouting the seed previous to planting does not succeed well early in the season, but does sometimes when the weather is favorable in the latter part. Cucumber seed is the tenderest of the vine kind, for if, after planting at the usual depth, wet weather should follow, it is almost certain to rot; if dry, it dries out; if, when favorable to their vegetating, and the plants have advanced so as to be breaking ground, a storm should occur, they generally perish; a northeaster of three or four days' continuance destroys the plants when young, and in some instances when more than a week old; if up too early, a late frost is apt to sweep them clean. Seed to vegetate requires to be near the surface of the wet soil, not buried deep into it; our ignorance of the weather which will follow after planting, causes most of our errors; when planted in a heavy soil, it is less liable to rot and dry out than in a sandy one, but the fruit is later. If it happens that there are more plants in a hill than we require, we find it an easy matter to eradicate them with the hoe and fingers, but it is not so easy to place them in the hills when deficient.

When the first rough leaves of the plants are about the size of a twenty-five cent piece, a cultivator is run through the rows both ways, and they receive the first hoeing; the plants are also thinned out, so as not to crowd each other. In hoeing, the soil between the plants should not be disturbed; large weeds, (if any,) be pulled out; fine soil drawn around the plants up to the seed leaves, so as to cover small weeds, and the hill made flat and not concave. We are careful not to hoe while the plants are very young, for if a storm should occur shortly after the operation has been performed, the hills soak in too much water, which is injurious. Ten or twelve days after the first hoeing, the plants (if good,) are thinned to six or eight in a hill, leaving the largest ones, and if possible three or four inches apart. About eighteen days after the first hoeing, or about the time when single blossoms open, we run a one-horse plough twice through a row each way, (if the ground is hard, three times,) throwing the furrow from the hills, and then commence the second hoeing, which is performed in the same manner as the first, care being taken not to earth up higher than the seed leaves, and to scrape out the crust between the plants, if the ground is hard or covered with weeds: they are, also, if the plants are fair, thinned down to five in a hill.

When the vines extend so that single ones meet each other between the hills, to prevent injury, they are carefully laid aside by hand, or with a short stick, and the cultivator for the last time is run once through a row each way. They then receive the third and last hoeing, the ground being loosened and drawn up around the hills with the hoe, and broken between the plants with the fingers. It is customary to leave five plants in a hill, standing from four to five inches apart, but some reduce them to four: have tried no experiment to test which is the best.

Cucumber vines will yield fruit about eight weeks, and the fields are picked over at least every second and sometimes every day. In picking, a light stick with a cross-piece framed to it so as to resemble the letter T, is made use of to push the leaves aside and more readily discover the fruit.

The insects which trouble and destroy the plants, are the black worm and striped bugs: the first is apt to be numerous in ground which was occupied the preceding year with red clover; they cut off the plants at or above the surface in the night, and are generally hunted out early in the morning, when their burrowing is fresh, and they lay near the surface, until the ground is cleared of them: the striped bug or yellow fly eats the plants in the day time, and is sometimes very destructive on land where a crust is formed on the surface, which being raised up by the young plants, affords them a harbor. The best remedy is, with the fingers to catch and destroy them in the morning, when the dew is on them and they are chilled, which prevents their flying and escaping as freely as when the sun has warmed them. Sandy land, having no crust to shelter these pests, is generally exempt from their depredations.

We are acquainted with the system of rotation of crops, and it has been practised among our farmers for years, but cucumbers as well as some other vegetables, do not seem to require it. I have a piece of about half an acre, on which I have cultivated them for the last ten successive years, ploughing in the usual quantity of street manure every second year, and they have flourished as well as on the adjoining ground, which has been similarly manured, and on which the crops have been changed.

The following is the quantity planted, produce and amount of sales, for the last four years, viz.

Year.	Hills planted.	Cucumbers sold.	Am't received.
1835,	6,000,	104,965,	$823 84
1836,	6,600,	99,670,	820 96
1837,	7,370,	130,735,	532 00
1838,	7,110,	118,600,	734 87½

During each of these years, large quantities of cullings, and, when unsaleable, good ones, were fed to the hogs and cattle, of which no account was kept.

Yours, TUNIS G. BERGEN.

Plan of a Garden.

King William county, Va. Oct. 6, 1838.

JUDGE BUEL—Not liking the plan of your garden, as laid down in the last [September] Cultivator, for several reasons, I have sent you a plat of mine, which is at your service, either to be placed before your readers, or thrown under your table, as may seem in your better judgment the most advisable.

It is the usual practice in the south, among moderate estate farmers to combine the flower and vegetable gardens. The desideratum among them, then, is, to lay off a garden which will accomplish the object in the simplest, neatest style. The one in question was laid off this last spring, and has been much admired. It is 60 by 80 yards—nearly an acre. The area is divided by two main walks, eight feet wide, intersected by a circle twenty-four feet in diameter. This, you will perceive, throws the garden into four divisions; each division is divided into four squares by six feet walks, which are again intersected by circles or octagons and diamonds, each twelve feet in diameter. A walk six feet wide runs the circumference of the garden, leaving a border next the paling of four feet. The centre circle is intended for a summer house of lattice work, to be covered with vines, such as the multiflora, &c.—the smaller figures to be devoted exclusively to flora, and decorated and adorned by fixtures, according to the taste of the individuals who may bestow most attention upon them.—There are sixteen squares for vegetables; the borders I shall sow in lucerne or flowers, as is the usual case.

A VIRGINIAN.

[Fig. No. 65.]

h h h h Border, 4 feet wide.

The walks round the octagons and diamonds 5 feet wide.

Lunar Influence.

Plymouth, (Conn.) Oct. 29, 1838.

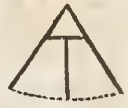
J. BUEL, Esq.—Sir—I have not been much of a star-gazer or moon-gazer, but have often heard it remarked that pork killed in the wane of the moon, would shrink away and waste in cooking. This I have always doubted, although I knew that some years my pork wasted more in cooking than others. This I attributed to some cause other than the influence of the moon, without being able to assign any cause. Last year, I fattened and butchered three hogs, all fattened together, though not all of the same litter. One was killed the first day of December last, weighing 238 lbs. and the other two the 26th of the same month, weighing 328 lbs. and 300 lbs. It will be seen that the first was killed in the new of the moon, and the two last in the old. The pork was salted in the same cask and in the same manner. The pork of the two last killed hogs wasted very much in cooking, either boiling or frying, so that it was noticed by all the family. The cook said, put ever so large a piece of pork in the pot or spider, and it would be very small when fit for the table. But it is entirely different with the pork of the hog first killed. It rather swells than shrinks in cooking. How to account for this difference, I do not know, except from the influence of the moon. The hogs last killed were early March pigs, and the other some older.

It is important to know the cause why meat sometimes wastes so much in cooking; and if the above statement of facts should give any information on the subject, or elicit any, I shall be well paid for my trouble. Very respectfully,

CALVIN BUTLER.

Ice Houses.

In the Cultivator for this month, is an article on the "Construction of Ice Houses." To those about to make them, it is an interesting one; still, it may be desirable to see descriptions of others, that they may have a choice of plans. Four years ago, I had one made, simple, cheap, and it has proved sufficient, thus: Dug a circular hole eight feet deep, the earth thrown out forming a bank of four feet high; the pit thus made, being tunnel shaped, eight feet in diameter at bottom, and thirteen feet at top of the ground; around the sides, placed white pine poles, of about thirteen feet in length, except the space for a door, close to each other, and inverted, without dressing them, save to make them of proper taper. Those of eight to ten inches thick at the buts, were put in whole; those of larger sizes split into halves, and the flat sides put to the bank; they are supported by resting on the bottom and sides of the pit; the buts were sawed to a level, and the earth thrown up on the outside to the upper ends. An octagon roof is formed by eight rafters of four by three, hemlock scantling, twelve feet long, resting on the buts of the poles, and framed into an octagon block at the top; eight intermediate shorter rafters of eight feet long, also resting on the poles in a line with the long ones, supported at top by a cross-piece framed to the adjoining long ones, thus: Used common oak lath, two feet apart, to nail the boards upon; covered with pine boards, tongued and grooved, the angles breaking on the long rafters. Door upright, four feet wide, five feet high, from ground level, and a cut out of the roof to allow this height. Jambs, to support the bank on each side, made of plank, nailed to posts set in the ground, and flaring to six feet. About forty wagon loads fills my house, where it keeps well. I use straw to about the thickness of a sheaf at the bottom, sides and top of the ice. What ice melts is mostly at the sides; the water is carried off the underside of the poles, and from the shape of the pit, as the ice settles it leaves no vacancy at the sides. At first, I put on a thatched straw roof; it proved a harbor for rats, and in one season they destroyed so much of it, that I had to substitute boards. I have shaded my ice house by an arbor of Isabella Grape vines, which gives us much fruit, and greatly improves the appearance of it, besides breaking the rays of the sun.



ROB'T WHITE, Jun.
Rumson Neck, Shrewsbury, N. J. 10*th mo.* 1838.

Millers' Tolls Again.

Rahway, Oct. 21, 1838.

Mr. J. BUEL—Dear Sir—On the 16th of October, I had two bushels of wheat, weighing 120 lbs. ground and bolted by Mr. John Florence, at his mills, under my inspection. When I called at the mill, Mr. F. was grinding rye, which he finished, and then put about one peck of corn in to clean the stones. When this was all ground out, he weighed my wheat, and put it in the hopper; the following is the weight of flour and bran, which it made, viz. 118¾ lbs. which deduct from the weight of the grain, leaves a loss of 1¼ lbs. in two bushels, or 120 lbs. of wheat, which of course, will make a loss of 10 oz on one bushel. I do not believe, the average loss in grinding 20, would exceed 7 oz. Now the mystery is, how to account for this loss. I will account for a part of it, in two ways, viz. first, that the dampness of the grain is absorbed by the heat, caused by the friction of grinding, [which dampness, or water, Blair says, is 900 times heavier than air.] Of this fact, any person may convince himself; by putting his hand up into the top part of the leader, that conveys the flour from the stones, he will find it wet, and pasted with damp flour. And in the second place, the flour coming from the stones hot, and perfectly dry, into the damp atmosphere, the finest and dryest of it will rise into the air; there remain until impregnated with its dampness, then settle in every part of the mill. I consider it much more philosophical, to attribute this loss of weight, to the dampness, or water, contained in the grain, than to suppose, as Mr. David Walton has, that it is all fixed air. He appears rather dissatisfied with my requiring the proof for the quantity of air he wishes to make exist in a bushel, or 60 lbs. of wheat, and wants to know, what loose air has to do with the just or unjust tolling of grain? I will reply, that it has nothing to do with the miller's toll; and if he will put a pair of artificial optics astride his nose, and look more attentively at my former communication, he will there see asserted, that if he confined a bushel of loose air in a bushel of grain, it would only add 1 oz. 9 dwt. to its weight: this is the point I am contesting. I wish him to prove that there is more air in any species of grain than the open portions of said grain will contain of loose air. The only way he can make it appear, is that it is condensed; which I will not admit without plain proof. I say it is confined, if there should any appear in the grain, but do not believe it to be condensed. There might be some probability of air being condensed in grain, provided it grew to the size of a pumpkin, and as hollow, and then diminished until it attained the size of wheat; but as wheat forms in a very small milky substance, and continues to expand until it ripens; I say, if it contains air at its formation, it has more room as the grain grows. I apprehend he will be disappointed if he expects to convert nine-tenths of the agricultural community to the belief, that the wheat they raise is even one hundredth part air. It is an established fact in philosophy, that air fills all space that is not occupied by any other matter, and one of its first principles is, that no two things can occupy the same place, at the same time. Now, this wise man has made a discovery that no philosopher has done before him, which is, that all solid bodies contain fixed air. I will quote, for his information, Blair's definition of solidity, viz. "Solidity is that property which every substance possesses, of not permitting any other substance to occupy the same place at the same time." I cannot favor him with the grinding of my wheat, as long as he makes a deduction of from one to five pounds per bushel for fixed air. Yours most respectfully,

WILLIAM A. STONE.

The Combined Effect of Heat and Water on the Temperature of the Atmosphere.

It is a law in the science of heat, "that all bodies, in passing from a rare to a dense state, emit caloric." It is found, also, that when any great change takes place in a body, as its passing from a solid to a liquid, from a liquid to a vapor, or *vice-versa*—a great quantity of caloric is either absorbed or emitted, according to its change; whether from a dense to a rare state, or the contrary, which previously remained latent and unappreciable. It is found by experiment, that water, in freezing, gives out 140° of latent heat, and the ice remains at the same temperature immediately after, as the water was immediately before freezing, viz. 32°. Ice in thawing, also, absorbs the same quantity to convert it into a liquid.

The quantity of water, therefore, on the globe, performs a most important office in equalizing its temperature. When the atmosphere is cooled to a temperature below 32°—the freezing point of water—water will begin to freeze, and in freezing, it emits caloric enough for every pound of ice to raise another pound of water 140°, or to make it so hot that we could with difficulty bear our hand in it. Not that it could be made actually to heat a pound of water to this temperature, because its heat could not all be applied to it: but it modifies the temperature of the atmosphere, when below 32°, just as much for every pound of water frozen as a pound of water would do, if heated 172°, and left to cool itself by radiation in the atmosphere, down to the freezing point.

Were it not, therefore, for the vast quantity of water on the earth, we might be scorched by the sultry suns of summer, or fatally chilled by the piercing blasts of winter. Our polar regions during the semi-annual night would be wide wastes of dreary desolation.—Vegetation would be totally destroyed, and all organic life, of whatever description, wholly laid waste. The return of day would bring with it the opposite extreme. The constant rays of the sun would operate without any thing on which to spend their force. As a consequence, the temperature of the earth would be very highly raised—probably above what organized life could possibly bear. As it is, water operates as a check to either excessive heat or cold, by receiving caloric and giving it out as nature requires.

Thus water forms a vast repository, (if I may so speak,) for this most important principle in nature, heat: without which, our globe would be but a mass of totally dead matter. When the sun retires to the southern hemisphere, and the temperature of our climate is reduced by the earth's radiation, so that vegetation is stopped, nature draws on her deposites in our oceans and rivers, by consolidating water to ice, so that the temperature of our atmosphere is prevented from becoming so much below the freezing point of water as it would were there no water, or were that water incapable of being frozen. When again the sun returns to vivify our hemisphere, the same quantity of heat is again returned to the water, by thawing the ice, and thus the deposite is made good.

As summer advances, and the rays of the sun might produce so much heat as to be deleterious to organic life, (as undoubtedly would be the case, were there nothing to counteract it,) water steps in again and undergoes another change. By this, its effects are still greater than in the preceding. In the transformation of water to vapor, about 1000° of heat are absorbed, and that vapor may still be no hotter than the water from which it was formed. That is, a pound of vapor contains about five times as much heat as a pound of water, at its usual temperature in summer, when both are apparently at the same temperature, and the thermometer would be alike affected by each. Evaporation is that process, of which heat is the actuating principle, that keeps up the constant circulation of the waters of the earth—that causes a continual flow of our rivers, which, continually discharging their contents into the ocean, never fill it; and that waters our fields, with refreshing showers to supply the wants of the vegetable and animal kingdoms. In a warm summer's day, vast quantities of water are vaporized. The Mediterranean sea, notwithstanding it receives the waters of numerous large rivers, still receives a constant supply from the main ocean at the straits of Gibralter, to keep up its continual evaporation.

There is no natural phenomenon, if we will study it and trace it to its causes, in which we cannot discover, in some degree, finite as are our powers, the wisdom of the Great Architect of Nature. This property of equalizing the temperature of our atmosphere, is not the only particular, in which this wisdom may be discovered in water. Were it not for its property of containing latent heat, all at once, on the approach of winter, our rivers, lakes and oceans would become so many frozen and solid masses. Not a liquid drop of water could be found when the atmosphere was below 32° Fahrenheit. Again, on the return of spring, these masses of ice would assume their liquidity in as short a time as they were before congealed. Snows from our mountains and hills would, almost instantly, as soon as the atmosphere became warmer than 32°, tumble in torrents from their sides, which would deluge every lower country and sweep every thing within their reach. As it is, when water is freezing, it is done very gradually; for there is a great quantity of heat to be radiated, even after it is so much cooled as to be cold as ice: and when the ice thaws, it has, not only to be heated, so that it is as warm as water is, before it will freeze, but it must receive 140° additional heat which remains latent in, or combined with the water, before it can be liquidated; and then it thaws as gradually as it freezes; and immediately after it is thawed, a thermometer placed in the water will not rise above what it was in the ice.

Another striking property of water, in which important consequences to us are involved, is, its being, when at a certain temperature, expanded by *cold*, in opposition to the general law of heat—water being, (I believe,) the only exception to that law. Water when cooled below 40° Fahrenheit, ceases to contract, in conformity to the general law, and expands as it is cooled below this point. Were it not for *this* property, in spite of its capacity for heat, it is probably that all the water in temperate climates, where we have a tolerable long winter, would be congealed in solid masses, so that all the heat of a summer's sun would not be sufficient to thaw it.

"Ice is the natural state of water;" and with equal propriety we might say, that a solid is the natural state of every substance. Without heat, the great vivifying principle in nature, and as it has been styled "the life and soul of the universe," the most volatile substances would condense to a degree of which we can form no conception. It is perhaps not impossible, extravagant as it may appear, that the hypothesis of Newton, *that our world might be compressed into the compass of a cubic inch*, would be realized by the total absence of heat alone. It is heat that keeps the gases in their gaseous state, that makes water liquid, and keeps our atmosphere from becoming solid, as really as it is heat by which we can reduce the metals to liquids, and make water assume the form of air. Philosophers have never yet been able to produce a substance totally void of heat, and it is reasonable to infer, that they never *can;* so that it is not possible to conceive the effects which *cold*, strictly speaking, would produce.

What the matter, or substance of heat is, does not come within the scope of our inquiry. It is a problem which has never yet been satisfactorily solved. We can study its phenomena and observe its effects; but we must remain, for the present at least, in the dark as to what *heat is*. It is known to possess vast expansive power. Certainly we can no longer question this power, when we are assured that it is the only force which can compete successfully with attraction. It is heat that keeps our globe distended to its present dimensions; and heat that drives our steam-boats and rail-road cars. It is heat that makes such a strong and delightful contrast between the gloomy desolation of winter, and the blithesomeness and verdure of spring and summer. It is heat by which we are enabled to overcome the strong cohesive attraction in the metals, and reduce them to liquids and dispel them in vapor. And, indeed, it is probable that, by a sufficient quantity of heat, every substance, even the most dense in nature, might be made to undergo the same successive changes which would result in their conversion into "thin air."

From the foregoing we learn the following facts for practical application.

1. The man who burns green wood, does it at a great loss. For, as green wood contains about one-third its weight of sap and water, enough heat must be employed to convert these liquids into steam and dispel them. Now all steam contains about 1000° heat, which is not sensible, and consequently cannot be of any use in warming the apartment.

2. The man who would heat his water hotter, after it boils in an open vessel, is foolishly wasting fuel. For all surplus heat, over enough to make it boil, is rendered latent in the vapor which is dispelled.

3. We learn also, why those towns adjacent to the sea and islands possess a greater uniformity of temperature than those places farther inland, and more remote from any large collection of water.

4. The above theory is practically acted upon, when gardeners, (as they sometimes do,) to preserve fruit trees from the effects of frost, connect them with straw ropes, having their ends immersed in a tub of water: and also by sprinkling vegetables with water in the evening, when there is a prospect of frost.

5. Substances which freeze at a temperature below 32°, as potatoes, apples, &c. may be prevented from freezing, by keeping them with water near them, in a confined situation. As long as any water remains uncongealed, such substances are safe. P.

Albany, Nov. 1838.

Remedy for Sprains, Bruises, &c.

As it frequently happens that severe swellings occur from bruises, sprains, &c., I take the liberty of sending you a recipe which has, in various instances within my own sphere of observation, produced the most rapid and extraordinary relief. It was tried a few days ago, upon the foot of a gentleman who was suffering agony from a violent sprain and afforded instantaneous relief. I have used it with great success in dispelling fistulous swellings upon horses. It has never with me failed to reduce the swelling, unless pus had formed. Its simplicity has caused it to be rejected by some, but as it can do no harm, and as the materials are at hand, it can at least be tried. It is a mixture of one pint of soft soap; a pint of good vinegar; a handful of common salt, and a table spoonful of powdered nitre; put them into a common white basin and bathe the part affected. I have never used it where the skin is abraded, as most probably violent pain would ensue. If, upon trial, you deem it worthy of publication, I shall be pleased to see it in the pages of the widely circulating Cultivator.

T. F. NELSON.

Virginia, Oct. 26, 1838.

A Looking-Glass.

J. Buel, Esq.—Dear Sir—When I was a boy, I can well remember how I used to be induced to wash my smutty face, by having a looking-glass held before my eyes. For the same purpose, I have extracted the following picture of "a farmer," from the writings of that most eccentric and excellent writer, "Samuel Slick," in the hopes that if any of your readers should happen to see any part of himself therein, that he will improve by the view. Here it is.

"* * * That critter, when he built that wrack of a house, (they call 'em a half house here,) intended to add as much more to it some of these days, and accordingly put his chimbley outside, to sarve the new part as well as the old. He has been too "busy" ever since, you see, to remove the banking put there the first fall, to keep the frost out of the cellar, and consequently it has rotted the sills off, and the house has fell away from the chimbley, and he has had to prop it up with that great stick of timber, to keep it from coming down on its knees altogether. All the winders are boarded up, but one, and that might as well be, for little light can penetrate them old hats and red flannel petticoats. Look at the barn; its broken back roof has let the gable eends fall in, where they stand staring at each other, as if they would like to come closer together (and no doubt they soon will,) to consult what was best to be done to gain their *standing* in the world. Now look at the stock; there's your "improved short horns." Them dirty looking, half starved geese, and them draggle-tailed fowls that are so poor the foxes would be ashamed to steal them—that little lantern jawed, long leg'd, rabbit ear'd runt of a pig, that's so weak it cant curl its tail up—that old cow frame standing there with her eyes shut, and looking for all the world as tho' she's contemplating her latter eend—(and with good reason too,) and that other reddish yellow, long wooled varmint, with his hocks higher than his belly, that looks as if he had come to her funeral, and which by way of distinction, his owner calls a horse—is all "the stock," I guess, that this *farmer* supports upon a hundred acres of as good natural soil as ever laid out door.—Now there's a specimen of "Native Stock." I reckoon he'l imigrate to a warmer climate soon, for you see while he was waiting to finish that thing you see the hen's roosting on, that he calls a sled, he's had to burn up all the fence round the house, but there's no danger of cattle breaking into his fields, and his old muley has larnt how to sneak round among the neighbors fields o' nights, looking for an open gate or bars, to snatch a mouthful now and then. For if you was to mow that meadow with a razor and rake it with a fine tooth comb, you could'nt get enough to winter a grasshopper. 'Spose we drive up to the door and have a word of chat with Nick Bradshaw, and see if he is as promising as outside appearances indicate.

Observing us from the only light of glass remaining in the window, Nick *lifted the door* and laying it aside, emerged from his kitchen parlor and smoke house, to reconnoitre. He was a tall, well built, athletic man, of great personal strength and surprising activity, who looked like a careless good natured fellow, fond of talking, and from the appearance of the little old black pipe which stuck in one corner of his mouth, equally so of smoking; and as he appeared to fancy us to be candidates, no doubt he was already enjoying in prospective the comforts of a neighboring tap room. Jist look at em—Happy critter—his hat crown has lost the top out, and the rim hangs like the bail of a bucket. His trowsers and jacket show clearly that he has had clothes of other colours in other days. The untan'd mocasin on one foot, which contrasts with the old shoe on the other, shows him a friend to domestic manufactures; and his beard is no bad match for the wooly horse yonder. See the waggish independent sort of a look the critter has, with his hat one side and hands in his breeches pockets, contemplating the beauties of his farm. You may talk about patience and fortitude, philosophy and christian resignation, and all that sort of thing till your tired, but—ah, here he comes. 'Morning Mr. Bradshaw—how's all home to day? Right comfortable, (mark that—comfort in such a place,) I give thanks—come, light and come in. I'm sorry can't feed your hoss—but the fact is, tan't bin no use to try to raise no crops, late years, for body don't git half paid for their labor, these hard times. I raised a nice bunch of potatoes last year, and as I could'nt get nothing worth while for 'em in the fall, I tho't I'de keep 'em till spring. But as frost set in, while I was down town 'lection time, the boys did'nt fix up the old cellar door, and this infarnal cold winter froze 'em all. It's them what you smell now, and I've just been telling the old woman that we must turn too and carry them out of the cellar, 'fore long they'll make some of us sick like enough—for there's no telling what may happen to a body late years. And if the next legislator don't do something for us, the Lord knows but the whole country will starve, for it seems as tho' the land now a days won't raise nothing. It's actually *run out*. Why, I should think by the look of things round your neighbor Horton's, that his land produced pretty well. Why, yes—and it's a miricle too, how he gets it—for every body round here said, when he took up that tract, it was the poorest in the town.—There are some folks that thinks he has dealings with the "black art," for't does seem as tho' the more he work'd his land, the better it got.

Now, here was a mystery—but an easy explanation of Mr. Slick soon solved the matter, at least to my mind. The fact is, says Mr. Slick, a great deal of this country is *run out*. And if it warnt for the lime, marsh-mud, sea weed, salt sand, and what not, they've got here in such quantities, and a few Horton's to apply it, the whole country would *run out* and dwindle away to just such great, good natured, good-for-nothing, do-nothing fellows as this Nick Bradshaw, and his wooly horse, and wooless sheep, and cropless farm, and comfortless house, if indeed such a great wind rack of loose lumber, is worthy the name of a house.

Now, by way of contrast to all this, do you see that neat little cottage looking house on yonder hummock, away to the right there, where you see those beautiful shade trees. The house is small, but it is a *whole* house. That's what I call about right—flanked on both sides by an orchard of best grafted fruit—a tidy flower garden in front, that the galls see to, and a most grand sarce garden jist over there, where it takes the wash of the buildings, nicely sheltered by that bunch of shrubbery. Then see them everlasting big barns—and by gosh, there goes fourteen dairy cows—as sleek as moles. Them flowers, honeysuckles and rose bushes, shows what sort of a family lives there, jist as plain as straws show which way the wind blows.

Them galls, an't 'tarnally racing round to quiltin and husking frolics, their feet exposed in thin slips to the mud, and their honor to a thinner protection. No, no—take my word for 't—when you see galls busy about such things to home, they are what our old minister used to call "right minded." Such things keep them busy, and when folks are busy about their own business, they've no time to get into mischief.—It keeps them healthy, too, and as cheerful as larks. I've a mind w'll 'light here, and view this citizen's improvements, and we shall be welcomed to a neat substantial breakfast, that would be worthy to be taken as a pattern by any farmer's wife in America.

We were met at the door by Mr. Horton who greeted my friend Slick with the warm salutation of an old acquaintance, and expressed the satisfaction natural to one habitually hospitable, for the honor of my visit. He was a plain, healthy, intelligent looking man, about fifty, dressed as a farmer should be, with the stamp of "HOMESPUN," legible upon every garment, not forgetting a very handsome silk handkerchief, the work throughout of his oldest daughter. The room into which we were ushered, bore the same stamp of neatness and comfort that the outside appearance indicated. A substantial homemade carpet covered the floor, and a well filled book-case and writing desk, were in the right place, among the contents of which, I observed several Agricultural periodicals. I was particularly struck with the scrupulously neat and appropriate attire of the wife and two intelligent, interesting daughters, that were busily engaged in the morning operations of the dairy. After partaking of an excellent substantial breakfast, Mr. Horton invited us to walk over his farm, which, tho' small, was every part in such a fine state of cultivation, that he did not even express a fear of "starving, unless the legislature did something, to keep the land from running out."

We bade adieu to this happy family, and proceeded on our journey fully impressed with the contrast between a good and bad farmer, and for my own part, perfectly satisfied with the manner that Mr. Slick had taken to impress it indelibly upon my own mind.

Mr. Slick seemed wrapped in contemplation of the scenes of the morning for a long time. At length he broke forth in one of his happy strains. "The bane of this country, 'Squire, and indeed of all America, is having TOO MUCH LAND—they *run over* more ground than they can cultivate—and crop the land year after year, without manure, till it is no wonder that "*it's run out.*" A very large portion of land in America has been "run out," by repeated grain crops, and bad husbandry, until a great portion of this great country is in a fair way to be ruined. The two Carolinas and Varginny are covered with places that are "run out," and are given up as ruined, and there are a plagey site too many such places all over New-England, and a great many other states. We hav'nt the surplus of wheat that we used to have, in the United States, and it'll never be so plenty while there are so many Nick Bradshaw's in the country.

The fact is, 'Squire, edecation is ducedly neglected. True, we have a site of schools and colleges, but they an't the right kind. That same Nick Bradshaw has been clean through one on 'em, and 'twas there that he larnt that infarnal lazy habit of drinking and smoking, that has been the ruin of him ever since. I would'nt give an old fashioned swing tail clock, to have my son go to college where he could'nt work enough to arn his own living, and larn how to work it right tu.

It actilly frightens me, when I think how the land is worked and skinned, till they take the gizard out on't, when it might be growing better every day.—Thousands of acres every year are turned into barrens, while an everlastin stream of our folks are streaking it off "to the new country," where about half on 'em after wading about among the tadpoles, to catch cat fish enough to live on a year or two, actilly shake themselves to death with that everlasting cuss of all new countrys, the fever and agur. It's a melancholly fact, 'Squire, tho' our people don't seem to be sensible of it, and you nor I may not live to see it, but if this awful robbin' of posterity goes on for another hundred years, as it has for the last, among the farmers, we'll be a nation of paupers. Talk about the legislature doing something, I'll tell you what I'd have them do. Paint a great parcel of guide boards. and nail 'em up over every legislature, church, and school-house door in America, with these words on em in great letters. "THE BEST LAND IN AMERICA, BY CONSTANT CROPPING, WITHOUT MANURE, WILL RUN OUT." And I'd have 'em, also, provide means to larn every child how to read it, cause it's no use to try to larn the old ones—they're tu sot in their ways.—They are on the constant stretch with the land they have, and all the time trying to git more, without improving any on't. Yes, yes, yes, *too much land* is the ruin of us all.

Although you will find a thousand more good things among the writings of "The Clockmaker," I hope you will not look for a *literal* copy of the foregoing. And if ever this meets the eye of the writer of the "Sayings and doings of Samuel Slick," I beg him to excuse me for the liberty I have taken with his own language. I remain your agricultural friend,

SOLON ROBINSON.

Experiment in Planting Potatoes.

Editor Cultivator.—Dear Sir—I have made a small experiment on potatoes this season, that may be useful. I selected a bushel of very small ones, and planted them in seven drilled rows, eleven rods long, the ground in fine order, ridged, and well cultivated during the growth.

Another bushel of largest size, I planted, one half in one row, whole, along side of the others, then cut the other half into three or four pieces each, and planted in two rows; the land and cultivation all the same.

The extreme drought that we have suffered, renders it unnecessary to speak of the amount of the yield, except comparatively.

The two rows of cut seed produced three baskets full—the one row of uncut produced two and a half baskets full, and the seven rows of small seed produced fourteen baskets full. But mark, like the seed, was the crop. The vines of the small seed were ever small spindling vines, and the tubers were likewise.—The vines of the uncut showed the rankest growth, but the difference in the general size of the tubers in the cut or uncut rows, was not much in favor of the uncut. Call the basket a bushel, and the result is easier stated. One bushel of small seed, produced fourteen bushels of small potatoes—half a bushel of large seed, planted upon one-seventh quantity of ground, produced two an half bushels of large ones—and half a bushel of large seed, cut, planted upon two-sevenths of the quantity of ground, produced three bushels of large ones.

The seed, when I planted it, was worth 75 cents a bushel—the crop, when dug, was worth 37½ to 50 cents a bushel—the cost of seed in each row of small seed, 10½ cents—the worth of the product 75—just seven fold in money and 14 in measure. The cost of the uncut seed 37½ cents to one row—the worth of the product $1.25, being worth 12½ cents more per bushel than the small ones, making three and one-third fold in money, and five in measure. The cut seed cost 18¾ cents to the row, and the product worth 75 cents, making four fold in money, and six-fold in measure.

If the experiment is a fair criterion to base an opinion upon, the result shows to my mind, the following data.

If seed is high, ground plenty, and the crop wanted for stock, plant small seed.

If seed is plenty, ground scarce, and the crop wanted for family use, and future seed, plant large seed, without cutting.

If seed is scarce, ground plenty, and the crop wanted for family use, and future seed, plant large seed, and cut them. Am I right in my conclusions?

These rows as above stated, 11 rods long, are at the rate of 78 to the acre, 3 feet apart. The large uncut potatoes were planted at the rate of 39 bushels to the acre; the product 195. The large cut, were planted at the rate of 19½ bushels to the acre; the product 117. The small ones were planted at the rate of 11 bushels to the acre; the product 156. For my own part, I shall in future plant large potatoes whole. I should like yours, and your correspondents' opinions and experiments. Your friend,

SOLON ROBINSON.

Lake C. H. Ia. Oct. 15, 1838.

Remarks.—The Conductor will at present only remark, that the choice between cut and uncut potatoes, should depend somewhat, he thinks, upon the kind of potato planted. Some kinds, having but few eyes, may advantageously be planted whole; while other kinds, having many eyes, as the Rohan, forty-fold, &c. are best planted in sets, or pieces. We have counted 47 eyes in a Rohan, all of which it is presumed, would grow, and give 47 stalks to a hill. It will at once be perceived, that instead of producing in size like the seed, the progeny must necessarily be small, both for want of food and want of room. In this case, we venture to say, if the tuber was cut into 20 sets, and each planted separate, the value of the product would be twenty fold greater than if the whole potato was planted in a single hill. We have chosen this strong case, the better to illustrate the distinction we would make. Small seed almost invariably produces small stalks, and small stalks are a pretty sure indication of small tubers.

EXTRACTS.

Science of Gardening.—*Continued.*

[*From the Alphabet of Gardening.*]

It does not appear to me to be at all necessary for understanding the scientific principles of gardening, to go minutely into all the points respecting the interior structure of plants, and the functions attributed to the several tissues, and vessels, inasmuch as those best skilled in such inquires are by no means agreed upon many particulars. The attention will therefore be more usefully directed to the points which have been best ascertained and least disputed.

RISE OF THE SAP.

The fluids taken up from the soil by the spongelets at the tips of the root fibres, are carried up into the main root in a manner not yet well understood, whether it be by minute tubes, or by oozing among the cells, as water is diffused through blotting paper or lump sugar. These fluids, as soon as they enter a plant, whatever may be the manner in which this is effected, take the name of sap, the rise of which into the stem is demonstrated by the ingenious experiment of watering with very thin coloured fluids, some of which are taken up, though the ordinary sap is for the most part without colour, and transparent like water. The yellow juice of celandine, and the milky juice of spurge are not sap.

In animals, the nutritive portion of the digested food which is taken up, as we have already seen, on the inner surface of the intestines, by the mouths of innumerable small tubes, is thence carried by the union of these into one[*] of considerable size, which conveys the whole into a vein,[†] where it is mixed with the blood. It is thence carried to the heart, by whose motion or beating it is thrown into a large vein,[‡] and carried to the lungs, where it is distributed into innumerable small tubes and exposed through their very thin membranes to the fresh air taken in by breathing. Here the blood takes from the air a portion of its oxygen, and at the same time parts with a quantity of carbonic acid gas, which is carried off by the returning breath: hence deteriorated by the loss of oxygen, and by having become loaded with carbonic acid. It is this deterioration, which renders it indispensable for all animals to breathe fresh air, as confined air is soon rendered poisonous and becomes fatal. The blood thus freed from superabundant carbonic acid, and united with a portion of oxygen, is collected by innumerable minute arteries which unite into one,[§] and carry it back to the heart, to be thence distributed to every part of the body, for the purpose of supplying fresh materials for the growth or repair of the several parts.

These things I have stated more at length, in order to point out the very different processes that take place in plants, which have nothing like the animal heart to impel the sap into circulation, for the pith in the centre of trees, though popularly termed the *heart*, performs no such office.

USE OF LEAVES.

The leaves, however, have been proved, by numerous experiments, to be in some respects similar in their functions to the lungs of animals, though very unlike if considered as organs. The sap, for instance, is spread out in a leaf, into small portions, as is the blood in the animal lungs; and for the similar purpose of exposing it to the action of the air.

It is important to remark that the air acts on the blood in the animal lungs always in the dark, whereas in acting upon the leaves of plants, it is by turns in the dark, and by turns in the light—and the results under these two circumstances are very different.

In the dark, leaves, like the lungs of animals, take in oxygen from the air and part with a portion of the carbonic acid gas contained in the sap; from which it is evident that they obtain a greater portion of this important material than is supplied by the water or the atmospheric air mixed with it, taken in by the roots from the soil.

It follows, that the air of a green-house, or any room or confined place where plants are kept, must be unwholesome during the night, from the air in such cases being deprived of its oxygen, and also loaded with carbonic acid gas. Consequently, flowers ought not to be kept at night in bed-rooms, though during sun-light they purify the air.

In the light, the sap which is spread over the upper surface of a leaf immediately under the thin, colourless, and transparent skin,[||] parts with a portion of its water in the form of vapor, and also with the oxygen contained in the carbonic acid gas, (which is composed of oxygen and carbon,) and as the oxygen goes off the carbon remains, while the sap, previously little less fluid than water, is converted into a sort of pulp,[¶] a considerable proportion of which consists of carbon. The use of this pulp, as we shall see anon, is, like the animal blood, to supply fresh materials, for the growth of the plant; and as the blood, after it has been acted on by the air in the lungs, passes from the veins to the arteries, so the pulp of plants is plausibly conjectured, but not proved, to pass from the upper to the under side of the leaf. The tubes or cells in which this pulp is lodged being of a yellow colour, and the carbon, according to Sennebier, of a dark blue, produce between them the green colour of the leaves and the younger bark, and hence the darkness of the green becomes a sort of test to determine the quantity of carbon separated from the sap, and also in some measure of tenderness and strength; plants being usually vigorous, hardy and tough, in proportion to their carbon, or, if Sennebier is right, in proportion to the darkness of their green. The term vigorous appears to be misapplied to plants of a pale colour, which grow too large and become dropsical.

It is, at all events, certain, that blanched plants are tender; that bulbs placed so deep as to blanch a large portion of their leaves before reaching the surface, are too weak, as I have experienced, to flower well; and that young leaves in the spring, before they acquire their full green, are readily injured by frosts and cold winds.

In accordance with these views, it may be stated that plants are of darker green in Italy, where the sun is seldomer overclouded, than in England; and though the grass has certainly a good colour in "green Erin," it is not, I think, to be compared with the beautiful green meadows in the Canton of Berne in Switzerland, where the sun-light is more intense from the general elevation of the country. In American forests, when the young spring leaves appear, they sometimes continue pale yellow for several weeks, from the haziness of the sky, but no sooner does the haze clear away, and the sun shine out, than the green deepens almost visibly. "The colour of the forest," says an eye-witness, "absolutely changed so fast, that we could perceive its progress; by the middle of the afternoon, the whole of these extensive forests, many miles in length, presented their usual summer dress."

It is a very curious fact connected with this subject, that, as it is on the upper surface of the leaf only where the sap is changed into pulp by the action of air and light, the leaf cannot be reversed, so as to place its upper surface undermost, and away from the direct light of the sky, without injury. When Bonnet accordingly placed leaves with their upper surfaces upon water, they withered almost as rapidly as in dry air.

Some practical gardeners, such as Lyon and Hayward, are disposed to question this circulation of the sap, but it has been proved beyond all doubt by experiment. Dr. Darwin plunged plants of spurge in water tinged red, and saw it rise through the leaf-stalk, and after being decomposed by the air and light, saw it return white from the edges of the leaf. T. A. Knight traced the returning pulp back into the leaf-stalk, and thence into the inner bark. He found also that if the leaves be stript from the upper part of a branch, the bark will wither as far as it is stript; and if a ring of the bark be cut out above and below a leaf, the wood in the part above the leaf does not grow.

It is therefore fair to conclude, that all the increase in growth arises from the leaves, that is from the pulp, prepared in the leaves by light and air, in the same way as all the increase in the growth of animals arises from the blood prepared in the lungs by the air, without light.

The doctrine held in some recent works of high pretensions, that the water given off by a plant is not produced "exclusively by the action of light and air," but "is *due*[*] to evaporation, or prespiration," which sometimes causes water equal in weight to that of the plant to be perspired in twenty-four hours, is quite erroneous. It is altogether owing to light or air.

The high importance of the leaves becomes thus manifest, and nothing will more enfeeble a plant than taking off its leaves in the growing season; though they are no longer necessary during the cessation of growth in the winter. Their fall previous to winter is not caused by cold; for some trees drop their leaves while the weather is comparatively warm, but in consequence of the vessels at the root of the leaf-stalk becoming gradually rigid and obstructed, so as to prevent the rise of the sap, or, at least, the return of the pulp. When a branch is in any way killed during the summer, its leaves do not fall, so that the killing of a leaf will not make it fall.

The slower growth of evergreens, and the difference of their pulp, as well as of the texture of their skin, render their leaves less subject to a general fall, which takes place only partially and by degrees. It is probably on account of the skin of the leaves becoming thicker and firmer from exposure to brighter sunshine, that our oak and other similar trees become evergreens in warm climates, as St. Helena.

DESCENT OF THE PULP.

That the pulp formed from the sap in the leaf, passes back through the leaf-stalk into the bark, has just been proved; but the best inquirers are not agreed upon the manner in which it is afterwards distributed so as to nourish all parts of the plant. It is sufficient to know the unquestionable fact that it does so. A portion of it certainly passes down through the bark to the very root, where it in all probability throws out, as would appear from the experiments of Brugmans and Mirbel, such refuse materials as could not be used, and something of this kind may be seen adhereing to the root fibres of hyacinths growing in water-glasses.

A portion of it, in its descent, must also pass off into the stem, probably, by what may be termed pulp-cells, or by rays or plates, popularly termed the silver grain.[*] The pulp-cells have been supposed to be designed as reservoirs for spare nutrient matter, somewhat like the fat of animals, which is similarly stored up.

SEASONS OF GROWTH AND ITS CESSATION.

Too little attention has been paid in books of science to the different circumstances of plants, during the several seasons of the year; and not a few errors have thence been the consequence. It is commonly stated, for example, that "the sap rises in spring and descends again in autumn," whereas we have seen that the sap does not descend at all, at least in the state of sap, and it is very clear that in proportion as the pulp-vessels in the leaf-stalks become obstructed with woody or carbonaceous matter towards the autumn, a circumstance indicated by the leaves becoming tinged with yellow, the quantity of descending pulp must be diminished, and the rise of the sap, from the same cause, must be interrupted.

The facts then, so far as at present ascertained, appear to be, that, from this obstruction in the sap and pulp-vessels of the leaf-stalk, the sap rises in gradually diminished quantities, till, at length, when the leaves fall, it almost ceases. I say "almost," for that it does not altogether cease to rise is proved by the buds and bark continuing alive and fresh, though they would infallibly wither and die, if the supply of sap, admitted to be very small, but indispensable to their healthy state, were cut off by removing the roots.

Certain animals which cease to eat on the setting in of winter, such as the squirrel, the bat, the snake, the frog, the snail, and numerous species of insects, continue to live in a sluggish and nearly motionless, state, very different from sleep, in the circumstances, particularly, of the very slow and scarcely observable circulation of the blood, and of breathing, whose rapidity is not very greatly affected during ordinary sleep.

The terms *dormancy* and *dormant*, therefore, are inaccurate, when applied to this state, which is better designated by torpidity and torpid. Such animals are found previous to winter to become unusually fat, as indeed is the case, at this season, with most other animals, owing in part to the loss of substance becoming less, as perspiration diminishes with the increase of the cold.

Now plants, in winter, seem to be in circumstances very similar to those of torpid animals, the circulation of the sap, like that of the blood, and the changes effected by air and light, like the process of breathing, being scarcely, if at all, observable. With respect also to the increase of fat, it is said by T. A. Knight, De Candolle, and others, that a larger proportion than usual of nutrient pulp accumulates in the root, and in the pulp-wood.[†] That this is the case with the buds of trees, with the bulbs of bulbous plants, and with the crown[‡] of the root of most perennial plants, and with the tubers of potatoes and dahlias, I think there can be no question.

In this state of torpidity, then, the greater number of plants continue during the winter; but the torpidity is more or less in degree according to the mildness or severity of the weather. I gathered a wild rose,[§] fully blown, in Musselburgh Haugh, in Dec. 1818; and if the branch of a vine whose root is planted in the open air, be introduced in winter into a green-house, it will push out leaves, while the branches without remain torpid. That it does not derive its nourishment from the air of the green-house, was proved by De Candolle, who found that the roots of a vine thus forced into leaf, exhausted the water of a bottle in which he placed them, while those of an adjacent vine not thus forced into leaf, took up very little, if any, water from a bottle.

As animals, revived from their winter torpidity by unusually warm weather, are more apt to be injured by the recurrence of severe cold than if they had continued torpid, a circumstance but too frequently witnessed in the case of hive-bees, so plants prematurely roused from their natural winter torpidity by warmth, to expand their buds, are almost certain to suffer by it, should severe weather afterwards ensue.

It is important to remark here, that, like the leaves, the smaller root fibres shrivel and fall off, or become detached from the main root, a circumstance, which has not hitherto received the attention which it well merits, both in a scientific and in a practical point of view. The fact is very obvious in the potato, the ranunculis and anemone, the dahlia, the carmyle,[||] and in all bulbs.

"The soil," says De Candolle, "is warmer than the air at mid winter;" (being always about eight degrees above freezing;) "this warmth rouses into life the trunks and roots then full of the nutrient pulp collected in the preceding summer; while, from this cause, new root fibres shoot out towards the end of winter. These, having all the freshness and activity of youth, display their energy by pumping up the moisture from the soil. The awakening of vegetation then arises from two causes,—the activity of the new root fibres which push the sap they have taken in onwards from behind; and the activity of the bark which draws it upwards. When it arrives at the leaf-buds it causes them to expand; but acts first on those at the summit of the branches, either because it can rise more easily in a perpendicular direction, or rather because the wood and bark of the upper branches is younger, and therefore more energetic."

---

[*] Technically, *Thoracic Duct.*
[†] Technically, *Subclavian Vein.*
[‡] Technically, *Pulmonary Vein.*
[§] Technically, *Pulmonary Artery.*

[‡] In Latin, *Corona*, or *Torqua.*
[§] In Latin, *Rosa spinosissima.*
[||] In Latin, *Orobus tuberosus.*

That these are not the only causes, it is proved by plants often expanding their buds in spring, when the cold is greater than in autumn, and bulbs and the tubers of the potato cannot be kept from shooting except in considerable cold. It may therefore be inferred that plants are endowed with, or acquire periodical tendencies, in the same way as we ourselves go to sleep and waken again at the periods to which we have become accustomed. This is farther proved by plants taken to climates differing from those where they have been produced. English apple trees, for example, when first taken to Canada, bloomed much too early, and had all their blossoms nipt with the spring frosts, till, after being inured to the climate they learned to bloom later; which our almond trees in England, brought from the warm banks of the Jordan, have never yet sufficiently learned, and hence those fine trees, whose spring blossoms are so delightful, are rarely fruitful.

Bulbs become torpid about the close of spring, and re-awaken into life in the autumn, continuing to grow during the winter.

It is worth remarking, that when the buds of a plant have been once awakened into expansion, and new root fibres have begun to form, they will go on even at a lower heat than would have served to rouse them at first, as was experimentally proved by Mirbel and Chevreul.

It is evident from the preceding facts and inferences, that the strength which a plant will show in the spring, and consequently its successful growth in the succeeding summer, will depend much on the store of nutrient matter which it has been able to prepare and store up, in the buds, the pulp-wood, the root, and more particularly in the crown of the root; an important consideration in pruning and forcing, as well as in most of the processes of gardening.

The Offices of Roots and Leaves.

[*From Madden's Chemical Reports.*]

Plants may be said to consist of two great parts, the root and the stem, with their various appendages. But since we are in this place merely to consider one function of vegetable life, namely, the function of *absorption*, or the manner in which plants bring matter, external to themselves, within the range of their vital actions, we may confine our researches almost entirely to the *roots* and *leaves*,—these being beyond doubt, the parts by which extraneous matter is first received into the plant; and, in the first place, let us examine the functions of the root.

The term *root* is generally considered to include all that part of the plant which is beneath the surface of the soil. This, however, is not strictly correct; for many plants possess what botanists call a *rhizoma*, or underground stem. The true root is that part of the plant which, from the instant of its bursting the coverings of the seed, begins to direct its course downwards (or towards the earth's axis,) "with a tendency so powerful, that no known force is sufficient to overcome it." Moreover, it differs from the stem in many of its characters; thus, it does not divide itself into smaller fibres in the regular manner, in which stems generally give off their branches. Again, it never produces leaves or scales; and another important distinction is, "that it never becomes green (at least in tissue) when exposed to the action of air and light, while all the other parts of vegetables, when thus exposed, assume that colour." The root is divided into the body and fibres, the latter of which will alone claim our attention. These fibres are furnished at their extremities with a remarkable structure, which, from its resemblance to a sponge, has been termed *spongiole*. It consists of an extremely loose texture, and is most probably merely "the newly formed" internal "tissue" of the root itself, deprived of its more dense covering, or *cuticle*, as it is termed. This opinion is very much strengthened by the well-established fact, that roots grow by their extremities only. In this manner the spongiole is always being renewed; and, what is of still more consequence, is never *long in one place*. On this account it is that plants which live many years (if not growing too near others of the same kind) are not liable to die from having exhausted the soil; or, in other words, are not liable to be starved to death; for it is evident that, by the constant *change of position* of the spongiole, which is the only part of the root by which nourishment is received into the plant, there must be a constant supply of food, so long as the soil around it contains any organic matter in a fit state for absorption. It has been shown, by innumerable experiments, that the spongioles, or absorbent extremities of the roots, cannot take up any thing but fluids; or, at all events, if they can absorb solids, they must be in such a minute state of division, that they would remain suspended in water, even for a considerable time, which is a fineness of particles far greater than will probably ever be attained by any *mechanical* means.

It has likewise been proved, that plants are capable of choosing to a *certain* degree, their food; or, in other words, of selecting those substances which are best adapted for their peculiar nature, and rejecting what would be injurious. This power, however, appears to be limited, as it is perfectly possible to destroy a plant by giving it poison by the roots. The root, moreover, has the power of *excretion*, or returning to the earth such matters as are either useless or injurious. From this last property of roots, we may draw two valuable conclusions; *first*, That in order to poison a plant, the substance used must be capable of acting rapidly, or it will most probably be rejected before it has had time to produce its effect; and *secondly*, that since plants reject substances *useless* and *injurious* to them, the soil where they grow may in time become so impregnated with such substances as to render it incapable of supporting the *same species* of plant any longer; or at least until such time as the rejected matter shall have been decomposed. This point will be enlarged upon when we come to treat of the rotation of crops. The next purpose which the roots of all land, and the majority of aquatic plants, serve, is obviously to fix it firmly in its place. On this account, we find, in *many cases*, that a certain proportion exists between the size of the stem and the root. This, however, is subject to exceptions. But, on the other hand, in all cases an obvious relation may be perceived between the *form* of the root and the kind of soil in which the plant grows. Thus, if two specimens of the same plant—some of the grasses, for example—be found growing, the one in clayey, the other in a sandy soil, it will be seen, on examination, that the root of the one growing in the sand is much more minutely subdivided, and contains many more small fibres, than the one which grew in clay; and the reason of this is obvious: We have already seen that the spongioles are the only absorbent parts of the root; that they exist only at the extremites of the smallest fibres; and, moreover, that they can take up nothing but what is presented to them in the form of solution.—Now, in the clayey soil, from its retentive nature, the soluble parts are not allowed to drain away; and hence the plant is supplied with food near at hand, and, consequently, a few short fibres are sufficient. On the other hand, plants growing in sand are frequently deprived of all fluid near them, by the sinking of the soluble matters through the loosely aggregated soil; in which case the plant would inevitably perish from starvation, were it not for the wise law of Nature, which provides against such calamities, by endowing the roots of plants, placed under such circumstances, with the power of shooting forth innumerable minute fibres in all directions, in order that advantage may be taken of every drop of moisture which falls in their neighborhood. Nor is it merely in the number of minute fibres that the roots of plants growing in sand differ from those which inhabit the stiffer soils. The form of the *body* of the root is distinct; thus, nearly all bulbous, and other large succulent roots—as the turnip, for example—require sandy soil; and moreover, some plants—as that species of grass named *Phleum pratense*, (meadow cat's tail, or timothy-grass)—change the form of the root, according to the soil they inhabit; thus, in stiff clays, the plant just mentioned has a fibrous root, whereas in sand it becomes bulbous, and assumes all the characters of *Phleum nodosum*. The explanation here is as evident as in the former case. The bulbs of the roots act as reservoirs of food for the plant; thus, in very dry seasons, these bulbs shrivel up, their fluids being all needed by the rest of the plant and hence withdrawn. So beautifully do we perceive in this, as in all other cases, that design and adaptation of means to specific purposes, which must impress even the most sceptical with the absolute existence of a *Great First Cause*. So much for the root and its functions.

Important and complicated as these may appear, the leaf performs offices of a much more obscure nature. In the words of the justly celebrated Lindley, "Leaves are at once organs and respiration, digestion, and nutrition. They elaborate the crude sap impelled into them from the stem, parting with its water, adding to it *carbon*, and exposing the whole to the action of air." To describe fully in this place these numerous operations, would not only occupy far too much space, but would, to a certain degree, be foreign to our subject, as all we wish to examine at present is, how the nutritious matter gets into the plant, putting completely out of the sight the question as to what becomes of it after it is absorbed. From the sentence above quoted, we find that *carbon* is added to the sap by the leaves. By this is not meant, however, that it is without that substance until it reaches these organs, but merely that an extra quantity of this element is hereby added to it. How, therefore, is this accomplished? We have already repeatedly stated, that carbon always exists in the atmosphere in the form of *carbonic acid gas*. Now, it has been ascertained that the leaves, while exposed during the *day* to the sun's rays, have the power of absorbing this carbonic acid, and afterwards decomposing it, the *carbon* being retained, and the *oxygen* given out again in the form of gas. During the *night*, however, or in the shade, no such change takes place. Carbonic acid, indeed, may be absorbed, probably in the form of a solution in water, as it is well ascertained that leaves take up moisture during the night; but it does not appear to undergo any decomposition: part of it, in fact, is given out in an undecomposed state; and as oxygen is removed from the air, at the same time that this evolution of gas is going on, it is supposed that plants have the power during the *night*, of absorbing oxygen, which dissolves part of their *carbon*, and re-escapes in the form of *carbonic acid*. Thus, we see that, during the night, the exact reverse is taking place to what was effected while the leaves were exposed to the rays of the sun. In the latter case, carbonic acid being absorbed, the carbon is retained, and the oxygen evolved; whereas in the former oxygen is absorbed, and carbonic acid given out. What is the ultimate effect of these complicated and apparently inconsistent changes, it is hard to say.—The fact, however, remains unalterable; and from it we may draw at least two very valuable conclusions: *First*, From what we have said with reference to the formation of *carbonic acid gas* during the burning of vegetable matter, and since it is well known to all that this gas is likewise contained in great abundance in the breath of all animals, it is clear that, unless there were some process in constant operation of removing it from the air, our atmosphere would soon become so contaminated with this noxious gas (choke-damp,) that it would be incapable of supporting life. Now, it has been conjectured that this constant absorption of carbonic acid by plants during the day, and the evolution of oxygen (the constituent of air most essential to life,) has the effect of preserving the healthy condition of the atmosphere. *Secondly*—But, on the other hand, it is equally important to remember that the reverse takes place during night; plants at that period *vitiating* the air; which accounts for it not being healthy to sleep in apartments where a great number of plants are growing. But to return from this digression. From the facts above stated, we find that the leaves absorb carbonic acid and water; and, for the present, we shall rest content with this, and proceed at once to consider of what the food of plants really consists,—now that we are so far acquainted with that important function exercised by plants—namely, absorption—by means of which they receive their nourishment. And, in the first place, we may very briefly show the analogy which exists in this particular between plants and animals; by doing which we shall be enabled to render the sequel much more intelligible. It is well known to all who are conversant with the functions of living animals, that after the food is received into the stomach it undergoes certain changes; one of the most important of which is its being rendered *soluble*, and afterwards is *absorbed* by a special set of vessels called *lacteals*, and is then carried to the lungs to be converted into blood. Now, the analogy is perfect, if we take into consideration that plants have no stomach, and, therefore all the preparation which takes place in the stomach of animals, has to be performed in the *soil*. Hence Greisenthwaite, a most ingenious writer on this subject, says, "The soil may be regarded as the stomach, the common receptacle of the food of plants, in which manure is coverted into substances that are soluble; and afterwards those soluble substances are absorbed by the capillary tendrils of the roots, in a manner exactly similar to that already observed of the *lacteals* of animals." A moment's reflection will at once, therefore, clear up all difficulties; for we perceive that the *spongioles* of the root act exactly as the *lacteals* of animals,—namely, they absorb the soluble matters prepared in the stomach (soil,) and carry it to the leaves to be converted into *perfect sap*, which process likewise corresponds exactly to the conversion of the matter absorbed by the lacteals into perfect blood.

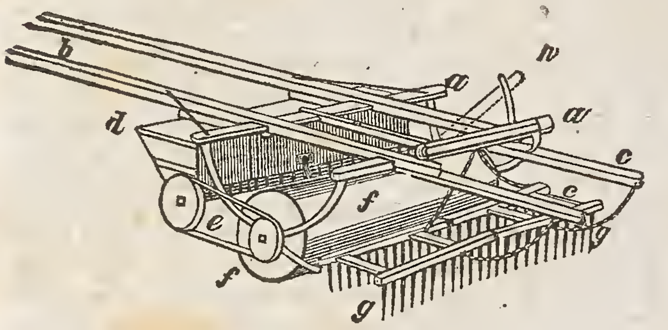
Description of a Grass Seed-Sowing Machine.

By Mr. Dudgeon, Broomhouse, East-Lothian.

[*From the Edinburgh Quarterly Journal of Agriculture.*]

This machine, of which a model was lodged by Mr. Dudgeon about twelve months ago in the Society's Museum, is an amplification of the common broadcast sowing-machine, so frequently used for sowing grass-seeds, as well as for its ligitimate purpose—the sowing of the different kinds of grain. Mr. Dudgeon seems to have devoted his attention to the construction of a machine, adapted to perform the processes of sowing, then rolling, and, lastly, harrowing at one operation; and he has been the first to bring such a method before the Highland and Agricultural Society. The machine, at full size, has been certified to perform these combined operations in a satisfactory manner.

[Fig. No. 66.]



In the annexed cut, this compound machine is exhibited in perspective, wherein the combination of the harrow and the roller are detailed along with the sowing apparatus, and may be shortly described as follows;—*a a* are the fore and hind bars of the top frame set at the distance of 2 feet apart, their length being about 7 feet 4 inches. To these are bolted down the horse-shafts *b* of the ordinary length, but having in addition, the extension bars *c c* bolted to the end of the shafts. The seed-chest *d*, 6½ feet in length, is appended to the lower side of the horse-shafts, immediately in front of the fore-bar, and may be fitted up in all respects similar to the common broadcast seed-chest, the spindle which carries the small discharging toothed wheels being put in motion by a belt or a chain passing over a pulley *e*, 12 inches in diameter, on the projecting end of the spindle; the belt or chain receiving its motion from another pulley of 9 inches diameter, placed on the axle of the roller, now to be described. The roller *f f* which is also 6½ feet in length, is about 18 inches in diameter, though this is not imperative, nor is the material of which it is made of any essential importance. The roller is supported by its journals in two simicircular bars of malleable iron, or they may be cast of iron, bolted to the extremities of the fore and hind bars *a a*. From the simicircular bars proceed also two stays for the further support of the seed-chest. The harrow *g g* is suspended immediately behind the roller; it consists of two frames, each 3½ feet in length, and 1 foot in width. These are jointed end to end, forming a harrow 7 feet in length, having only two rows of tines. The tines are set at 2½ inches distant, and, as the tines of the one row alternate with those of the other, they will make a rut at every 1¼ inch. The direct suspension of the harrow is effected by means of chains from the movable bar *h*; this being jointed at the one end is capable of being raised from the horizontal position to the position *h*, or to any intermediate point, and retained there by a pin passed through a quadrant over which the bar moves; by this means the harrow is regulated as to depth, while by means of a link from the simicircular bars, and by the chain from the extremity of the extension bars *c c*, it is duly stayed in a proper position, while it has sufficient freedom of swing to insure its useful effect. The joint at the middle of the harrow allows it to accommodate itself to the rounding of the ridges when required. The lever seen in the middle of the top frame is, through its connection with another lever on the back of the seed-chest, used for opening and shutting the orifices, and for regulating the discharge of the seed, by moving a long slide plate in the usual manner.

It may be remarked of this machine, that the particular succession here shown, that is to say *sowing*, *rolling*, *harrowing*, is not considered essential to its success; and that any other, as *rolling*, *sowing*, *harrowing*, may, under different circumstances of soil and management, be found equally successful.

Prevention of Mildew or Rust.

The following account of a successful experiment, in destroying mildew in wheat, is from the Rev. Mr. Cartwright, and is copied from the Edinburgh Quarterly, and from a paper on the diseases of cultivated plants, by G. W. Johnson, Esq. Although the application demands some labor, that labor is not to be put in competition with the value of the wheat crop. We have confidence in the authority and in the efficacy of the antidote; and recommend the prescription to our farmers for trial.

"I and a neighbor of mine have applied it as a remedy for the mildew in wheat, with the most unequivocal success. I first made the discovery about two years ago. My experiments at that time were upon a very limited scale. They have this year only extended over an acre and a half, but under circumstances that leave not a shadow of a doubt of salt being an absolute specific for mildew, in the most aggravated stages of the disorder. Of this I will state to you a convincing proof. In the year 1818, I found a few ears of wheat, which I conceived to be a new and improved variety. From these ears I raised as much wheat as last year planted a piece of land 4 feet wide, and 100 yards in length. The produce I had promised Mr. Coke, and to augment that produce, I had the ground, previously to planting, highly manured; and as soon as the wheat came up, I gave it a good dressing with soot, and this dressing was repeated once or twice. In consequence of this superabundant dressing, the wheat, as might indeed have been expected, was as rank as the wheat you may observe growing accidentally upon a dunghill, which never fails to rot upon the ground, without bringing a single grain to maturity.

"The mildew made its appearance on this particular part of my field, while the straw was quite green, and the grain in a milky state. Notwithstanding the danger that might be apprehended to the wheat itself, from its being thus succulent, I ventured to give it a dressing with salt and water. As a heavy shower of rain fell a few hours afterwards, the dressing was repeated the next morning.

"The proportion of salt to the water, one pound in a gallon, laid on with a plasterer's brush, the operator bearing a pail of the mixture in one hand, and the brush in the other, making his casts as when sowing corn; or else with a common watering-pot, which, being swung with great force, throws the water very rapidly. Two men will get over about four acres a-day, the one to spread, the other to supply the mixture.

"The result was, that the mildew was completely subdued, and the wheat went forward to maturity, and although the sample was not so bold as it might have been, it was sound and marketable. In other parts of the field, where the mildew shewed itself, not under the aggravated circumstances described above, but as it usually appears, the wheat was not in the least injured by it, after the salt and water were applied; it was indeed as fine a sample as could be grown. Both mine and my neighbor's wheat were examined by many practical farmers, who are so decidedly convinced of the efficacy of my remedy, that they intend never to be without a reserve of salt, ready to meet the enemy the moment he appears.

"The effect of the salt upon the mildew, to those who do not consider the manner of its operation, is truly astonishing; I believe it to be instant death to the fungus; this, however, is certain, in less than forty-eight hours the straw nearly recovers its original colour and brightness. The certainty and celerity of its operation, I account for thus: The mildew, it is now well ascertained, is a parasitical plant, of the fungus tribe, the principal constituent of which is water; when salt, therefore, is applied to them, the aqueous particles are immediately absorbed, and their vitality destroyed. The action of salt upon mushrooms, as in making mushroom catsup, confirms this theory."

Mr. Johnson adds—"I can afford decided testimony to the efficacy of the cure recommended by Mr. Cartwright; but I would add these precautions. The safest quantity of salt per gallon is eight ounces, and then the application may be rendered more effectual by frequent repetition, without any danger of injury to the plants. If the application is not made during a clouded day, it is best to defer it until the evening.

"Some have recommended a rope, held at its extremities by two men, to be drawn up and down each ridge of the infected crop, to remove the fungus; and there is no doubt that this treatment is partially effectual, for the parasite is removed wherever it comes in contact with the rope, but the points of contact necessarily are limited."

Nothing is Annihilated.

The researches of chemists have shown, that what the vulgar call corruption, destruction, &c. is nothing but a change of arrangement of the same ingredient elements, the disposition of the same materials into other forms, without the loss or destruction of a single atom; and thus any doubts of the permanence of natural laws are discountenanced, and the whole weight of *appearances* thrown into the opposite scale. One of the most obvious cases of apparent destruction is, when any thing is ground to dust and scattered to the winds. But it is one thing to grind a fabric to powder, and another to annihilate its materials: scattered as they may be, they must fall somewhere, and continue, if only ingredients of the soil, to perform their humble though useful part in the economy of nature. The destruction produced by fire is more striking; in many cases, as in the burning of a piece of charcoal, or a taper, there is no smoke, nothing visibly dissipated and carried away; the burning body wastes and disappears, while nothing *seems* to be produced but warmth and light, which we are not in the habit of considering as substances; and when all has disappeared, except perhaps some trifling ashes, we naturally enough suppose it is gone, lost, destroyed. But when the question is examined more exactly, we detect, in the stream of invisible air which ascends from the glowing coal, or flaming wax, the *whole* ponderable matter, only united in a new combination with the air, and dissolved in it. Yet, so far from being thereby destroyed, it is only become again what it was before it existed in the form of charcoal or wax, an active agent in the business of the world, and a main support of vegetable and animal life, and is still susceptible of running again and again the same round, as circumstances may determine; so that, for aught we see to the contrary, the same identical atom may be concealed for thousands of centuries in a lime stone rock; may at length be quarried, set free in the lime-kiln, mix with the air, be absorbed by it from plants, and, in succession, become a part of the frame of mryiads of living beings, till some concurrence of events consigns it once more to a long repose, which, however, no way unfits it from again resuming its former activity.—*Herschel on the Study of Natural Philosophy.*

Young Men's Department.

"What is Education?"

We commend to every young reader, who aspires to the good things of life—as wealth, reputation and happiness—the following extract, which we make from an article on education, in the North American Review. It is worthy a careful perusal,—of a re-perusal—and of being treasured up in the memory. It exhibits the true foundation, if not the only one, upon which any young man can expect to rear a superstructure of substantial usefulness.

"What is education, such education as deserves the name? Not the getting by rote set forms of words which may be altogether barren of profitable fruit; no, nor barely storing the memory with the information of facts, however extensive and useful.—An abundant stock of these, judiciously laid in, may doubtless prove of wonderful advantage in the after occasions of life. But education truly and faithfully accomplished, is the full and well-proportioned development of all a man's physical, intellectual, and moral capacities; such as sends him into the conflict of his earthly probation, a sound mind in a sound body, to fulfil the dictates of a sound heart. Training, aptly administered to this end, fosters and confirms all virtuous dispositions, checks and finally eradicates all unworthy propensities. The scholar learns to scorn ignoble objects of pursuit, and wisely bends his undivided energies, with an ingenuous ardor, to effect the liberal purposes of a comprehensive benevolence. He places his supreme happiness in the solid satisfaction of duty well performed. He knows how to choose the right; and, having made his election, his understanding and all his corporeal faculties, operate in their several functions in due subordination to realize his will. He is nerved for the fight, he can breast himself manfully against every assault, he will triumph victoriously over all opposition, for he feels himself strengthened to every good word and work, both in the inner and outer man. 'I call, therefore, a complete and generous education,' says Milton, 'that which fits a man to perform justly, skilfully, and magnanimously, all the offices both private and public, of peace and war.'

"Under such instruction he will grow up to understand and realize his position in the universe, and his relations to his fellow creatures, and what it is incumbent on him to be and to do, by virtue of their mutual dependencies. Society has done much for him. It has raised him above the level of the brutes, and he owes to society a return,—a large return,—vastly more than he can ever pay, though he were a Bacon or a Newton, a Lafayette or a Washington; but his inability to repay all does not release and cancel the debt of gratitude.

"There is an indefeasible obligation upon every man to do something for the world he lives in. He should ever bear it on his conscience to discharge this duty. With the blessing of God, he should say to himself, 'The world shall be somewhat better that I have lived in it.' He who does not say this, in sincerity and truth, is no nobler than the beasts that perish. Morally he is beneath them; for they act up to their light, and feel no responsibility for which they are not ready to give an account, while he lives in the daily sense that his part in the world's work is unperformed. While he yields no fruit, he only cumbers God's vineyard; and, when he is cut down, but few will mourn over him.

"Far otherwise is it with him in whose daily meditations philanthropy is ever present as a governing principle. Who are the truly useful? To whom is the world indebted for those magnificent benefactions, which have blessed millions and generations,—improvements in government, advancement in religion, and in civilization? To whom are mankind indebted for the noiseless but resistless progress of good principles, whereby greater changes are effected in the condition of the whole human family, than have grown out of the efforts of the mightiest conquerors, or than have followed the most renowned revolutions of empire? To those whose moral education has fixed in their hearts permanent and actuating principles of conduct. There have been men of erudition, whose memories were libraries for the singular benefit of their associates, but whose learning died with them. There have been men of forecast and sagacity unsurpassed,—our own times have witnessed some of them,—who, having no rule of action except their own immediate advantage, have been governed by circumstances, instead of subjecting circumstances to their own control. But those who are widely and lastingly useful, are the men upon the stability of whose moral character reliance can be safely reposed. With such the sense of duty is habitual; and, therefore, even if they cannot boast of uncommon talents, extensive acquirements, or a broad field of action, still, as all their acts have the same tendency, their influence is always in the same direction: and, operating silently and unseen, is the cause of meliorations in the moral tone of society, perceived after a few years by all, but understood while they are going on only by a few reflecting observers. With such, the performance of duty is pleasant, because all their desires are trained to accordance with the moral sense; and they, therefore, do good naturally, and as of course, with less effort and internal struggle than the bad experience when they do evil.

"It has sometimes been strangely questioned, whether a popular sound morality might not be the natural offspring of ignorance and delusion, and whether a refined education did not weaken in the soul the sanctions of religion, and relax those bonds which hold together the compact of society. But were it not blasphemy against the God of truth to doubt, that the illumination of the intellect with the radiance of wisdom infuses into the heart the love of virtue? Goodness is the imprint which the sense of truth stamps indelibly upon the character. All noble thoughts are types of noble action. From the contemplation, to the imitation of ideal excellence, the transition is natural and easy. The divine light of moral science sheds a clear distinctness over our true interests, and shows the path of duty marked in a bold outline. Before its purifying beams, all evil thoughts and low desires vanish as the noonday splendor dissipates the mists of the valley. The well-educated man stands before the world the image of his Maker, having attained as nearly as may be to the perfection of his moral nature. He exhibits not merely a speculative but an active virtue, and all beholders are constrained to confess that wisdom is justified of her children.

"If indeed the security of the public morality reposed on the public ignorance, if delusion were the palladium of our well-being, miserable would be the condition of humanity; for ignorance is of the earth, earthy, and must soon pass away. But the progress and prosperity of our race rest on no temporary and precarious reliance. When delusion has died of old age, truth will still flourish in eternal vigor. She renews her youth like the eagle. When to mortal eyes she appears vanishing for ever, behold, like the young sun rejoicing in his course, she rises again. She is not of created things, and is therefore exempt from their destiny. God's well-beloved daughter knows neither age nor decay. Before the work of creation began, she was with the Father of all things; and, when Time shall have ceased to be, she will stand before his throne, and still bask in the living light of the ineffable presence.

"It is not merely poetry, but the ultimate result of all moral argument, that, 'true self-love, and social, are the same.' 'This is the foundation of all human wisdom,' says Le Père Buffier, 'the source from which all virtues, purely natural, flow, the general principle of all morals, and of all human society, that while I live with other men, who equally with myself desire to be happy, I must try to discover the means of increasing my own happiness, by augmenting that of others.' Cicero regarded it as the basis of ethics, 'ut eadem sit utilitas uniuscujusque et universorum.' A higher authority than Cicero has established a whole code of duty upon the maxim, 'Do ye therefore unto others as ye would that others should do unto you.'

"It is impossible therefore that the study even of temporary interests should derogate from the just influence of moral principles, at least while conducted on broad and comprehensive views; since there is no contrariety between them, but rather a strict conformity, the more evident as those interests are better understood.

"But it is not to be forgotten, that the cultivation of the intellect is but a part, and not the most important part of a good and perfect education. The preeminent worth of moral cultivation should be strongly impressed on every parent and teacher. With a little care, many salutary precepts may be instilled into the minds of youth, such as shall deserve to be treasured up among the guiding maxims of their lives, and meditated upon as the fundamental principles of practical wisdom. These, being firmly rooted in their memories, will help them to form solid and substantial characters, which in after life will stand the test of every trial. Correct habits must be acquired, the sovereignty of conscience over the whole man must be established, the power of self-reliance must be gained, and the sentiment of independence nourished. Imbued with virtuous principles, and having learned to prize above all price, and to preserve at every hazard, the testimony of an approving conscience, the youth goes into the world armed at all points. To gird him with this panoply should be the endeavor of his moral education.

"Almost the best defence, at least one of the strongest safeguards of morality, is the feeling of independence. If the world thinks that to be right which you think to be wrong, follow your own opinion, and preserve your self-respect. Consider that you would rather be honorable and despised, than be honored and despicable. If the world holds you in light esteem because it misundertands your character, every mark of disrespect which it bestows upon you is a certificate of the beauty and excellence of those virtues in which it erroneously supposes you to be deficient. But if the world, while it knows your character, disesteems you, because the principles that regulate your conduct are above the received standard of morality, and it is incapable of appreciating them, retire within your own bosom and enjoy that serene consciousness of rectitude, which can sustain undisturbed the hoarse clamor of popular invective. He who has the fortitude and the constancy to do this, and to go on steadily in the path of duty visible to his eyes alone, experiences not merely that tranquil satisfaction which a sense of obligation fulfilled brings always with it, but a loftier, nobler, prouder pleasure, even the most exalted of which our nature is susceptible here on earth, that unalloyed felicity which is the perogative of integrity invincible amid allurement or peril. The stern and solemn joy which bore the martyrs triumphant and exulting through their trials, which supported them and gave them the victory over shame and anguish and death itself, is the due reward of original and peculiar virtue, of virtue manifested in spite of temptation,—in spite of what is still harder to be resisted, ridicule, opprobrium, and scorn.

"He who is educated as all the youth of a Republic should be, his virtuous dispositions corroborated into fixed habits, his knowledge of his own powers and capacities perfected into a modest but confident self-reliance, his heart steeled with the inflexible determination to guard and preserve unviolated the sanctity of his own self-approval, while an enlightened conscience with a distinct and unequivocal bidding calls him onward and upward in the path of a purer morality, though the blandishments of fashionable example draw him backward and downward with the witchery of sympathy, will never yield to the seduction, nor be disobedient to the dictates of that monitor whose precepts are not set at nought without punishment. He will not follow the multitude to do evil against light and conviction. The mean and cowardly abandonment of principle for precedent, the despicable dereliction of that course, straight though solitary, in which the very instinct of a noble spirit urges him on, never suggests itself to his contemplation as within the range of possible alternatives. He will not sacrifice that pure delight which neither the smiles of the world can give, nor their frowns take away. He will not surrender himself an unwilling and a miserable slave to the tyranny of custom, a servitude which becomes every day more and more intolerable, which exacts compliances still more and more degrading, which never loosens its hold till it has reduced the spirit, created to be free, to a grovelling dependence on the decisions and caprices of others.

"With youth so educated, we should have none of that dissipation, without relish, endured, under a secret disgust, for fashion's sake; none of that servility of manners, the corruption engendered in the dotage of feudalism, preposterously imported into the wholesome simplicity of a vigorous republic; no prevarication in business, no equivocation in professions, no cant in criticism, no shuffling in politics, no temporizing in morals, no hypocrisy in religion. We should live in an honest and straight-forward world. Far distant though the dawning of this millennium may be, it is none the less desirable to hasten it onward; and though it were taken for certain, that neither we nor our children should ever enjoy the full fruition of so blessed a state, we should none the less strive for the nearest approach that we can attain to it."

"Wealth is not only fleeting; it is neither the sole, nor the best foundation on which to rest our hopes of happiness, even while it lasts. Respectability of character is of far higher value, and much less likely to be lost through the caprices of fortune. It would be a waste of words to show, that an unspotted moral life must confer respectability, and that respect derived from whatever qualities, without this, must be short-lived and of little worth. Equally self-evident is it, that those who live in the constant practice of moral duty, though wealth and respect should both desert them, have internal resources for consolation of which they cannot be deprived. He who possesses a conscience void of offence is passing rich, whether he has much or little of this world's goods. He who is not afraid to be alone with is Maker, is independent of the smiles or frowns of the world. The sunshine of prosperity, the tempest of adversity, neither seduce nor terrify his steadfast soul. The basis on which his happiness is fixed, the immovable, imperturbable basis of a good conscience, he owes to a good moral education."

Chemical Catechism—Chapter VI.

[*From Parkes's Chemical Catechism.*]

OF ALKALIES.

What is the nature[*] *of an alkali?*

The alkalies have an acrid and peculiar taste; they change the blue juices of vegetables to a green, and the yellow to a brown; and have the property of rendering oils miscible with water. They are incombustible, but may be rendered volatile by great heat. They are soluble in water; form various salts by combination with acids[†]; and act as powerful caustics when applied to the flesh of animals.[‡]

How many alkalies are there?

There are three alkalies; two of which have been called *fixed* alkalies, the other the *volatile* alkali.

Which are the fixed alkalies?

The fixed alkalies are potash[§] and soda.[‖]

Why have they been called fixed *alkalies?*

Because they will endure great heat without being volatilized; and yet in a very high temperature, they are dissipated in vapor.

What substances enter into the composition of these alkalies?

Till lately the fixed alkalies were considered to be *simple* substances, no one having been able to decompose them; but they are now found to be *compound* bodies.

Have we any historical account of the discovery of these substances?

Potash was known to the ancient Gauls and Germans; and soda was familiar to the Greeks and Hebrews. This latter substance was known to these ancients by the name of *nitrum.*[¶]

What is the origin of potash?

Potash is chiefly procured by lixiviation from the ashes of burnt wood, and other vegetable substances; but as it exists in minerals and earths, there is reason to believe that plants receive it from the earth, during vegetation: hence it may be proper to discard the word *vegetable* entirely, when speaking of this substance.

What is the origin of soda?

Soda is generally procured from the ashes of *marine* plants;[**] but its great depository is the ocean, soda being the base of sea-salt, or muriate of soda.

---

[*] To a person who has not had an opportunity of examining an alkali, no written description that can be given will convey any correct idea of the taste or properties of this class of bodies: let the pupil, therefore, procure a specimen of each kind, before he enters upon this chapter. The juice of the gooseberry and the lemon, and many other vegetable substances, will remind him of the general properties of the acids: but having met with nothing analogous to the alkalies, it will be necessary for him to *taste* and examine one of these bodies in order to acquire any thing like a just idea of their nature. Let him form potash or soda into a neutral salt, by saturating it with one of the acids, and he will perceive still more of the nature of these bodies.

[†] Potash becomes comparatively mild by its union with carbonic acid; and the most caustic soda, if united to corrosive muriatic acid, forms muriate of soda, our mild tea-table salt.

[‡] If a piece of animal flesh be put into a strong solution of potash or soda, it will immediately be acted upon by the alkali, and soon be entirely dissolved.

The alkalies have a great affinity for water: it is therefore probable that their causticity is owing to this circumstance, water being so abundant in animal bodies. If the alkalies be dissolved in a large portion of water, their caustic qualities are diminished, though not in any measure destroyed thereby.

[§] This alkali was formerly procured by burning vegetables in large iron pots; hence it acquired the name of *pot*-ash.

[‖] Soda acquired its name from the plant *salsola soda,* which grows on the Spanish coast, and is burnt for its preparation.

[¶] This substance is found native in Egypt, and is there called *natron;* a name not much unlike that which it bore among the Jews and Greeks.

[**] The *salsola soda,* which grows among the cliffs on the sea-coast, is said to be endowed with the property of decomposing sea-salt, and that by some process of vegetation it separates the muriatic acid and absorbs the soda. Hence it acquired the name of *saltwort.* This plant is collected by the Spaniards with great care, and burnt for the manufacture of BARILLA, which is a considerable article of commerce. Thus Nature has providentially furnished the inhabitant of the otherwise barren coast with a source of employment, and has enabled him to supply the interior with an article of indispensable necessity, for ages before the science of chemistry could afford him other means of decomposing muriate of soda.

> "The *saltwort's* starry stalks are thickly sown,
> Like humble worth, unheeded and unknown."
>
> *Charlotte Smith.*

How is it that marine plants give out soda, while those which grow in the interior of the country afford potash?

This has been accounted for by supposing that these marine vegetables have the power, during vegetation, of decomposing sea-salt, and retaining the soda in their constitution.

Is soda found in any other state?

Soda combined with carbonic acid is found in great plenty in the natron beds of Egypt,* and in the East Indies: it occurs also in various other parts of the world, though never in a state of purity, and enters into the composition of the *sodalite* and of several other minerals.†

What are the distinguishing properties of these two alkalies?

The fixed alkalies are very similar in their general properties; but are easily distinguished by the variety of salts which they form with the acids; and by potash being more deliquescent than soda.

Is there any chemical test by which you can distinguish these two alkalies?

There are many; but a solution of the ore of platina in nitro-muriatic acid will answer this purpose most completely.

What are the chief uses of these alkalies?

The fixed alkalies have various uses in surgery and medicine: they are the bases of several salts; are employed much in the arts:‡ and are of great importance to the analytical chemist.

How are the fixed alkalies employed in the arts?

The fixed alkalies are used in large quantities by the glass-maker,§ the dyer, the soap-maker, the colour-maker, and by various other manufacturers.

In a former chapter, we noticed the use of fixed alkali in making glass:—What is the use of it to the dyer?

The alkalies are known to have the property of altering the hue of most colours; they are therefore employed with this view by the persons who are engaged in this trade.

Why are the alkalies employed in making soap?

An alkali is an essential ingredient in soap, as it is the only article capable of converting tallow or oil into a saponaceous substance, and enabling it to combine with water.*

Why are fixed alkalies employed in making colours?

Many colours are now manufactured in this country which cannot be made without an alkali: thus, animal matters are always incinerated with an alkali to form Prussian blue; a fixed alkali is also employed as a flux in the formation of the potter's blue from cobalt; and what are called French and mineral greens are made by precipitating copper from its solutions by means of these alkalies.

What are the other uses of these alkalies?

They are employed in making alum; in bleaching linen; in scouring wool; and in many other processes too various to be enumerated.

From whence is this country supplied with these articles?

The greatest part of the potash used in this country comes from America and Russia; but the *kelp* of our own coasts, and the *barilla* of Spain and of the islands of Teneriffe and Sicily, furnish us with most f our mineral alkalies.

Are these alkalies sold in a state of purity?

No: both potash and soda always contain carbonic acid* and water; and are often contaminated with earths, sulphur, and other impurities.

Have alkalies any peculiar affinity for sulphur?

Both potash and soda, as well as ammonia, have a strong affinity for sulphur; they combine by trituration or heat, and form *sulphuret* of alkali, formerly called *hepar sulphuris*, or "liver of sulphur."

What is the nature of sulphuret of alkali?

Its colour is similar to that of the liver of animals; its taste is acrid and bitter; and it has the property of decomposing water.

How are the alkalies of commerce purified for the use of the chemist or manufacturer?

Potash or soda is generally mixed with a portion of quick-lime to divest it of carbonic acid, and then lixiviated in proper vessels to obtain a solution of the caustic alkali, free from other impurities. When it is required *perfectly* pure for nice purposes, the alkali is dissolved in alcohol, and purified by a peculiar process.

Are the fixed alkalies ever used in a state of combination with carbonic acid?

Carbonic acid gives potash and soda the property of crystallizing readily; it also renders them mild, and fit for purposes in which caustic alkali would be improper; hence carbonate of potash is employed in medicine, and carbonate of soda for washing and other domestic uses.

What is the chemical name of the volatile *alkali?*

It is called ammonia.

What are the properties of ammonia?

Ammonia when uncombined with water, or any other substance, exists in the state of gas, and is then so extremely volatile as to exhale at all known temperatures. Its volatility is diminished in some degree by combination with water, still more so by combining with carbonic acid, and most when combined with the mineral acids. In the gaseous state it has a remarkably pungent smell, it instantly extinguishes flame, and would be fatal to any animals that were obliged to breathe it. It is lighter than atmospheric air in the proportion of 6 to 10.

As this alkali is a gaseous substance, how can it be applied in the arts?

Ammonia has an affinity for water, with which it readily combines, and forms *liquid* ammonia; in which state it is generally used.

What is the composition of ammonia?

Ammonia is a compound of hydrogen and nitrogen, in the proportion of about one part of the former, and four parts of the latter, when calculated by weight, or of one measure of nitrogen and three of hydrogen if calculated by volume.

Is this alkali capable of being decomposed?

Yes; ammonia may be decomposed by the electric spark. Oxygen gas will also decompose it by the assistance of heat, and then nitrous acid and water will be the results. If passed over red-hot charcoal, it will combine with part of the charcoal, and form *prussic acid*.

What is the effect of galvanism on ammonia?

A very different result may be obtained if ammonia be decomposed in contact with mercury, by means of galvanism; for in this case a metallic substance of a very uncommon nature may be separated from this alkali.

How is ammonia procured?

All animal and vegetable substances, when in a state of putrefaction, will furnish ammonia: this alkali is, however, generally procured in England by a dry distillation of bones, horns, and other animal substances.

What are the uses of ammonia?

In a liquid state ammonia has various uses in our manufactories, and in medicine; it is a valuable reagent to the chemist; and when combined with carbonic acid it takes a concrete form and beautiful white colour, being then the article known in commerce by the name of *volatile salts*.

Are there any other uses to which ammonia is applied?

Ammonia is serviceable in dyeing, and in staining ivory; but its principal use is in making the muriate of ammonia, of which it is the basis.

How is ammonia formed into muriate of ammonia?

Muriate of ammonia is formed by combining ammonia with muriatic acid. It is known in commerce by the name of *sal-ammoniac*.

Muriate of ammonia being formed by two gaseous substances, how does it acquire solidity?

It may appear surprising that the union of two gases should produce a hard ponderous body; but this may be attributed to their loss of caloric. The bases of these gases having a greater affinity for each other than they have for caloric, they combine intimately whenever they come in contact; and the compound having less occasion for caloric than the separate ingredients, the caloric is given out, and a solid is produced.

What are the uses of sal-ammoniac?

Sal-ammoniac is employed in many of our manufactories, particularly by dyers, to give a brightness to certain colours; also by braziers, tin plate workers, and others; and in medicine.

From whence was sal-ammoniac procured before it was made in this country?

Sal-ammoniac was formerly brought from Egypt sufficient for the supply of all Europe; but it is now made in various parts of Great-Britain, particularly in Scotland, where it is formed by a peculiar process from soot; and also from a variety of refuse animal matter.

Is ammonia capable of entering into any other combinations?

Yes: ammonia is capable of forming salts with most if not all of the acids.

Can you recapitulate the origin of the different alkalies?

The volatile alkali is procured from bones and other animal matters; potash or vegetable alkali from the ashes of weeds and burnt wood: and soda or mineral alkali from the ashes of some marine plants, also from sea-salt or muriate of soda.

What is the natural inference from a consideration of the nature and production of the alkalies?

The reflection which naturally arises from a consideration of this subject is, that the original organization of matter, whereby the effete recrementitious parts of animals and vegetables are made capable of producing useful and powerful substances, evinces, that infinite Power and Wisdom, united with consummate Beneficence, can effect the most *important* changes, by the most *unlikely* agents; and can convert to valuable purposes, substances which to us appear totally useless and inert.

Most of the peasantry in the Shetland Isles, and in the Highlands of Scotland, are supported by collecting sea-weeds, and burning them into KELP, an article which produces great revenues to the lairds of those districts. Many of the wretched inhabitants of those dreary regions have nothing to depend upon for subsistence, but a miserable pittance, which they acquire in this employment.

* The natron lakes of Egypt annually produce a large quantity of mineral alkali. In summer the water of these lakes is evaporated by the sun, which leaves a bed of natron generally two feet thick; and this is broken up by wedges, and packed for the European markets.

† Soda is one of the substances found in the bile of animals. Whenever this alkali occurs native, it is always in a *mild* state; and as it cannot combine with oils to form soap, unless it be *caustic*, this causticity is given it for these manufactories by artificial means. It is worthy of remark, that Nature has furnished the bile with soda in a state of *causticity*, which gives it the property of combining with and saponifying the fat or oily substances taken into the stomach, and rendering them soluble in the other animal fluids. What account can be given of this deviation from the usual course of nature, but the important purpose which it serves in the animal economy?

‡ The greatest consumption of the fixed alkalies in this country is in the manufacture of soap. They are also largely employed in bleaching, and in the manufacture of glass. Soda and potash are also both used in washing, and for other domestic purposes; as they powerfully unite with all greasy substances, which they render soluble in water.

§ It is curious to observe, that the alkalies combine with *transparent* olive oil, and produce *opake* soap; and that they unite with *opake* sand to form *transparent* glass. How various are the properties that have been impressed upon those primary materials of the universe, that were intrusted to man for the promotion of his convenience and comfort!

‖ To make soap, it is necessary to employ a fixed alkali in a *caustic* state. In this country, the business is usually conducted in the following manner: Spanish barilla or Scotch kelp is broken in pieces, or coarsely ground by a horse mill: and, when mixed with a sufficient quantity of quick-lime to absorb the carbonic acid, the whole is thrown into large wooden or iron vats, and covered with water. In great works, these vats are generally of cast iron, and sufficiently capacious to hold three or four tons of alkaline ashes. At a proper time, the water, impregnated with the caustic alkali, is let off into iron receivers below, and the vats are covered again with water, which, after standing a sufficient time, is let off as before. This liquor is called soap-boilers' lie. When a sufficient quantity of this is prepared, Russian or English tallow is put into a large iron boiler, and melted with a portion of the above-mentioned alkaline lie. At first, the tallow appears liquid like oil, but during its boiling it acquires by degrees consistence as it saponifies. When the alkali is uniformly combined with the tallow, the weak liquor is pumped from beneath the soap, and fresh lies are added in their stead. These are boiled as before, till the soap exhibits certain appearances well known to the manufacturer; it is then cooled down, and poured into deep wooden frames, 15 inches wide and 45 inches long; where it remains till it has acquired a sufficient degree of solidity to be cut up for sale. It is the *alkali* which gives soap its detergent quality, and which renders it soluble in water. The tallow serves to moderate the sharpness of the alkali, and to prevent its injuring the hands of those who use it.

In making yellow soap, resin is used in the proportion of about one part to three or four parts of tallow. The resin makes the soap more detersive, and enables the manufacturer to sell it cheaper. Common fish oil, when its price permits, is also used in yellow soap.

Potash is the alkali used for soft soap, the manufacture of which is a distinct and separate trade in this country. A solution of this alkali in a caustic state is boiled with fish oil; and when the oil is sufficiently saponified, and a complete union of the materials formed, the *whole* is poured into small casks for sale, the water having combined with the oil as well as the alkali.

* The potash and soda of commerce contain nearly one-fifth of their weight of carbonic acid, beside lime, silica, and other impurities.

THE CULTIVATOR:

A MONTHLY PUBLICATION, DEVOTED TO AGRICULTURE.

I KNOW OF NO PURSUIT IN WHICH MORE REAL AND IMPORTANT SERVICES CAN BE RENDERED TO ANY COUNTRY, THAN BY IMPROVING ITS AGRICULTURE.—*Wash.*

VOL. V. NO. 3, WASHINGTON-ST. ALBANY, N. Y. JANUARY, 1839. No. 11.

Conducted by J. BUEL, of Albany.

TERMS.—ONE DOLLAR per annum, to be paid in advance. Subscriptions to commence with a volume.

Special Agents.—L. & R. HILL, Richmond, Va.; BELL & ENTWISLE, Alexandria, D. C.; GIDEON B. SMITH, Baltimore, Md.; JUDAH DOBSON, bookseller, D. LANDRETH, and M. S. POWELL, seedsmen, Philadelphia; ISRAEL POST, bookseller, 88 Bowery, ALEX. SMITH, seedsman, P. WAKEMAN, office of the American Institute, Broadway, N. York; HOVEY & Co. Merchants' Row, Boston; ALEX. WALSH, Lansingburgh, and WM. THORBURN, Albany, gratuitous agents. For general list of agents see No. 12, vol. iv.

The Cultivator is subject to common newspaper postage.

☞ Price of the published volumes, 50 cents per vol. stitched—the four volumes bound together, $2.75—bound in two volumes, $3—the four vols. bound each separate, $3.25.

THE CULTIVATOR.

TO IMPROVE THE SOIL AND THE MIND.

☞ All subscriptions discontinued in February, unless renewed by payment in advance.

☞ An Advertising Sheet, ☜

☞ Will accompany our next number. The edition is 20,000 copies, circulating in every state and territory of the Union. Advertisements and notices for the Farmers' Directory, must be forwarded to us before the 20th instant.

☞ Annual Agricultural Meetings.

☞ The New-York State Agricultural Society, and the New-York State Agricultural Convention, are both to meet in Albany, on the FIRST TUESDAY IN FEBRUARY next. The Society will meet in the City Hall, at 11 A. M.; the Convention in the Assembly Chamber, at 4 P. M.

It is hoped that every county society, and every county, will be represented at these meetings, either by delegates, or by patriotic individuals. Much, as relates to the improvement of agriculture, and to the substantial interests of the state, may result from these deliberations. Men congregate with alacrity, from remote parts of the state, and at great expense, to compass party or sectarian purposes. Why not display a like zeal when the interests of a whole community are the objects of concerted operation? Surely if there is one business which more than another tends to benefit the entire state, it is the great business of agriculture—it is this which, directly or indirectly, most multiplies the comforts and substantial enjoyments of all classes. Let all, then, cherish this interest, and encourage its improvements.

American Society for the Diffusion of Useful Knowledge.

We know nothing of this society, except what has appeared in its publications. We have not made its proceedings the subject of inquiry, nor have we any personal acquaintance with the gentlemen who appear to manage its concerns. When we saw a list of fifty volumes, professing to be published under its sanction, recommended for the use of common schools, and virtually endorsed by Gov. Marcy and Secretary Dix, as one of the guardians, though self-appointed, of the agricultural community, we examined the list of books recommended, and declared our opinion freely and honestly—that it was *wholly unsuited to form the* BASIS *of a common school library, for an agricultural population.* Reflection has rather strengthened than weakened this opinion. But when we received from an esteemed friend, whose communication we published in our November number, a letter explaining the causes of the omissions of which we complained, with pamphlets detailing the disinterested and benevolent professions of the society, and giving, as officers and members, the names of many of our most distinguished citizens, we felt a confidence, that the objects of the association were truly patriotic and praiseworthy; and that although nothing had been done, in the first series of publications, to diffuse useful knowledge in the great business of agriculture, or other branches of productive labor, yet that something efficient would be done in the coming series. We consequently commended the society to public patronage, and invited our brethren of the type to co-operate in their labors of usefulness.

But since the publication of our last remarks, intimations deeply affecting the character of the association, and tending seriously to impair its usefulness, have reached us from remote parts of the Union—from New-Hampshire and from Kentucky. These intimations are sufficiently explained in the communication which we this day publish from a Concord correspondent, whose name is withheld at his request, though we feel authorized to give it to any one who may feel aggrieved by the facts he alleges. Reports like those stated in this communication are abroad. If they are well founded, they should be known, for we profess to be uncompromisingly hostile to any attempt to deceive the public in matters of such deep interest. If they are not true, the sooner they are met and put down by indubitable testimony, the better; so that whether they be true or false, the accused party has no cause of complaint; because the society should not longer suffer under unjust imputations, if innocent; nor should the public be imposed upon, if the charges be true. We do not deny the right of individuals or associations to speculate in books as well as in merchandize or lands. We ask only that they shall show their true colours.

We consider the course we have adopted in this matter imposed by duty. We shall be ready, nay anxious, to correct any erroneous impressions which these remarks, or those of our correspondent, may create upon the public mind, whenever we can do it with strict regard to truth.

Premium Crops.

We publish to-day three communications which have claims to premiums offered by us for the most profitable crops of corn and ruta baga. Two of these give the culture, product and profit of corn, and the other of the Swede. One of the corn crops gave a product of 118½ bushels—and an estimated profit of $87.71 per acre; and the other a product of 116 bushels, and an estimated profit of $91.96. The ruta baga yielded at the rate of 1,230 bushels per acre, and an estimated profit of $175.80. We invite the farmer, who by the old slovenly mode of culture, seldom netts as much from five or ten acres, as these spirited farmers have netted from a single acre, to pause, and scan the causes which produce this wonderful difference in the profits of farm labor. We presume 40 bushels is a high estimate for the average produce of an acre of corn. Then three acres of common corn would yield about as much as one acre of first rate. Then what is the difference in the expense of the two? The common crop will cost three times as much as the good crop, because it requires three times the labor to plough, hoe and harvest three acres that it does one acre. The only difference that we can perceive, is in carrying out the manure and spreading it. The good farmer carries it out to feed his corn crop—the bad farmer leaves it to rot and waste in his yard, while his corn is starving for want of it. Estimating the average expense of culture, therefore, at $15 per acre, the one expends $45 for 120 bushels of corn, to say nothing of rent, taxes, &c. and his crop, therefore, costs him at least 37½ cents the bushel.—The other expends $15, exclusive of drawing out and spreading his manure, and gets 118 bushels of corn. His crop costs him about *thirteen* cents the bushel, or about one-third as much as his reckless neighbor pays for his. The manure of the bad farmer must ultimately be hauled out or lost; and it is as valuable after having fed the corn, as it would have been if summer yarded. The extra fodder of the good crop, will more than pay for any extra labor that may be required to harvest it.

The modes of culture, &c. of the two crops noticed to-day, it will be seen, were alike in four important particulars:—

1. They were planted on a grass ley.
2. They were heavily manured with unfermented dung.
3. They were managed entirely with the cultivator and hoe, no plough having been employed in dressing the crop.
4. The crop, stocks and corn, was cut up before the grain had ripened.
5. The hills were not earthed.

These are all deviations from the common practice, and the results show, that they are beneficial ones.

The ruta baga crop is also worthy of attention. If an acre of ground, with an expenditure of $30, including manure, can be made to grow 1,230 bushels of ruta baga, 70 lbs. to the bushel, it is certainly an object worthy the consideration of the farmer. If a bushel, or 70 lbs. of ruta baga, is equivalent to 20 lbs. of good hay, for all kinds of neat cattle, the 1,230 bushels, the produce of an acre, would go as far in the economy of feeding, as nearly 20 tons of hay—which we should not ordinarily expect from less than ten acres. But take half or quarter of this estimate, and it shows the crop to be valuable.

The Philosophy of Pruning.

We apprehend that the common practices in this branch of rural labor are not altogether based upon a sound philosophy. The animal structure, we all know, is admirably adapted to its wants, to its habits, and to its uses. There is no surplussage—no useless incumbrance—all is necessary to fulfil the designs of nature. From analogy, as well as from the system and order which every where pervade the visible creation, is it not reasonable to infer, that every part of the vegetable structure is alike essential to its well being? Are not the branches and leaves as essential to the tree, as the limbs and lungs are to the animal? Who will say otherwise? Nature produces nothing in vain. Although we may assist in carrying out her designs, we cannot cross her purposes without suffering the penalty imposed for a violation of her laws.

No part of a plant can be affected without affecting the other parts. Roots and branches reciprocally produce and nourish each other. If a tree has part of its roots destroyed, the branches which these supplied decay; and when some of the branches are destroyed, some of the roots perish also. The extent and form of the one, will in a measure ever correspond with the extent and form of the other. If a young tree is kept close pruned, divested of its limbs and foliage, it is soon stunted in its growth, the wood becomes carious and diseased, and the plant is short-lived. If, therefore, we destroy the equilibrium—which nature has established, between roots and branches, by greatly diminishing the one or the other, we thwart her designs, and mistake our interest. Every branch has its roots—its mouths—in the soil, to supply it with the elements of its food; and every root has its branch and its leaves—its lungs—in the air, to convert these elements into food, for the joint benefit of them both and of the stem. One cannot attain growth without the co-operation of the other. Without the roots the plant cannot obtain the elements of food; without the leaves those elements, if taken into the system, are of no benefit; but, on the contrary, like the undigested food upon the animal stomach, generate disease, rather than promote health and vigor. Every leaf performs its office in the process of nutrition and growth; and, other circumstances being alike, the increase in the growth of the plant, will be in the proportion to the number of healthy leaves: if one half of these be destroyed, the growth will be but one half as great as if the whole had remained—if complete defoliation takes place, the growth will entirely cease. Hence pruning decreases growth, in proportion to the extent or severity with which it is practised.

"Whenever a tree has a live spray cut from it, an injury is inflicted on that tree that can never entirely be repaired. Every wound received is stored up; and if wounds be constantly added, they will accumulate to a degree too great to be borne, and the tree will sink under its infirmities. It is useless to attempt to transfer the timber of the boughs to the stem, or to confine the growth of timber entirely to the stem. However desirable it may be to the pruner, to have all the growth diverted to the increase of the stem, he never will be able to effect it. He may, like the dog, snap at the shadow, and lose the substance; but never will he be able, by pruning off the boughs, to increase the growth of the stem one jot. No; the size of the stem will be in proportion to the head it has to support. The stem is not, as he may imagine, a production formed merely for the use of man; it is the canal, or passage, in which the juices pass between the roots and branches; and the size of this passage is always in proportion to the offices it has to perform. If the number of branches [meaning to include leaves] be increased, the quantity of sap passing between them and the roots will be increased; a greater space is necessary for the increased quantity of sap, and consequently the stem is increased. Let the head of the tree increase, and depend upon it, there will be a corresponding increase of the stem.

"It is said to be right to cut away a small proportion of the weaker branches, and turn the current of the descending sap more abundantly into the stem. It is hard to understand what is meant by this explanation of the effects of pruning. Does the sap descend down the stem till it arrives at the weaker branches, and then ascend up them and increase their size, instead of that of the stem? If so, the weaker branches would soon become the stronger; or rather if trees have the property of sending the sap from the strong branches to the weaker all the branches would be equally strong. The descending sap, on reaching the weaker branches would become ascending sap. And if the small branches be considered obstructions preventing the descent of the sap, the large branches must be greater obstructions. But where does the sap descend from? Pruners forget, that they cannot cut a live spray from a tree without lessening the quantity of its leaves. Their theory is founded in error, and all their reasoning is false."—*Ballard, in Farm. Mag.*

This explains what often seems enigmatical to superficial observers in vegetable economy, viz. that moderate sized trees from a nursery, have ordinarily a much thriftier and healthier growth, and arrive sooner to a good bearing state, when transplanted, than trees that are very large. In the former, the natural proportion between the roots and the branches is preserved,—the former being taken up nearly entire—the sap vessels are filled, and the growth is but partially retarded. While in taking up very large trees, whose roots have greatly extended, the mouths of the plant are seriously diminished, the sap vessels contract and become indurated, in consequence of the diminished supply of sap—and the tree must acquire new roots, and a new sap-wood, by a slow process of growth, ere it can flourish with its accustomed vigor. The same evil results from cutting off the entire top of a tree. It is deprived of its elaborating organs; and although the root may send up the elements of food, they cannot benefit the plant for want of leaves to convert them into vegetable blood. It is no argument against this position, that deciduous trees spontaneously develop foliage and flowers in the spring. There is a store of elaborated sap laid up in autumn to effect this. Strip a tree in June, when this store is exhausted, entirely of its leaves, and the tree will not grow, and will probably die. The stem, at least, will sustain serious injury. The nurseryman knows, that after an apple, pear or plum stock has been cut down and grafted upon, the heart-wood becomes unsound if the graft fails to grow, and the whole stock dozy and in a manner worthless for a future scion, and that it will not grow a particle above where it sends off succors.

The tendency of pruning to generate disease, and to shorten the life of trees, is illustrated in the appearance of old orchards, which have been injudiciously pruned. Wherever a limb is split off by winds or accident, it exposes a diseased heart-wood; and this disease at the heart spreads to the roots and branches, and induces premature death. The natural duration of the apple tree is believed to be more than one hundred years; and yet how few are found in a healthy state at fifty years? Mark the contrast, in soundness of wood, in vigor of growth, and in duration of life, between the apple, and other frequently pruned trees, and those trees, whether fruit or forest, which are left to luxuriate naturally, without the artificial aid of the pruning knife.

If pruning be prejudicial to growth and longevity, why then, we may be asked—why prune at all? We answer, for utility, to give beauty, and to improve and increase the fruit.

In natural forest growth, trees attain height, and a straight clear timber form, from their crowded situation; and as the lower branches become useless they die and fall off. But in cultivated grounds, or where there is ample room for roots and branches to spread, this does not take place; and hence the propriety of pruning here to obtain a good stem for timber, or a handsome top for shade and ornament. Often there are two or more leading shoots striving for the mastery, and unless they are shortened, or taken off, there will be two or more stems, of diminutive size, instead of one stem, of larger size. We may therefore prune shade trees to improve their form, or to please the fancy, and timber trees to improve the bole; but in neither case do we either increase the growth, or prolong the life of the tree.

"As the twig is bent so will the tree incline," is literally true in regard to pruning. We may give almost any form to trees which fancy may conceive, by beginning early, and persevering with the pruning knife or shears, as is witnessed in clipped hedges, and often in ornamental and garden grounds. We may make them dwarfs or standards, or give them a thin or dense foliage, at our pleasure. They may be trained or cut into the shape of animals, into geometrical forms, or architectural or sculptural compositions.

We prune fruit trees to improve the fruit, and to induce a bearing habit. The roots of trees take up from the soil a certain quantity of vegetable food, call it geine, or humus, or organic remains, or what you please—it has constituted parts of vegetable structure, and is convertible, by natural processes, into wood or fruit, or both. If the tendency of the plant is to wood, as is generally the case with all healthy young trees, the fruit will be sparce and inferior, at least till the tree has attained to mature size. On the other hand, if the tendency to growth is checked, by poverty of soil, disease, or judicious pruning, the tree will be brought into a precocious state of bearing, and, in the case of judicious pruning, produce more and better fruit.

In pruning or training to induce a fruit-bearing habit, the object is to check the uninterrupted, and we may say natural, descent of the elaborated sap to the root, by encouraging a horizontal, instead of an upright, growth of the branches, when the tree approaches the bearing age. This causes a stricture in the descending sap vessels, at the bifurcation, or junction of the branches with the stem, and a consequent accumulation of elaborated sap in the branches, to generate fruit buds, and to swell the fruit, The same object is sometimes, though injudiciously, effected, by taking out a narrow circle of bark, or by ligatures, to prevent the descent of the elaborated sap. Hence the upright shoot is often cut out, particularly in the apple tree, and the branches are trained horizontally, diagonally, or in a half inverted position, as on walls, espaliers, and in the *en queneille*, or distaff form of training. These operations have also a tendency to improve the quality of the fruit, by giving it a better exposure to the kind of influences of the sun, air and light, all essential to its due maturity and high flavor. Nature provides for the propagation of the species, by producing perfect seed, leaving to art the labor and contrivance of enlarging and enriching the pulp or fruit. All fruits may be improved from their natural state, by artificial culture, though nothing may be added thereby to the intrinsic value of the seed, or natural duration of the tree. The seeds of the wild crab, or wild pear, are as good to sow for stocks, to graft or bud upon, as the seeds of the cultivated varieties of these fruits; and indeed, according to Dr. Van Mons' theory, which his practice seems to have confirmed, they are the best from which to start new varieties.

Prune, therefore, when necessary, to improve timber; prune for ornament; prune to improve the fruit: but do not prune in the hope of accelerating growth or of prolonging life. And in all your prunings, cut while the wood is small, and spare to the tree all the foliage you can consistent with the object you have in view. By pruning when the tree is young, and pruning often, we may secure a handsome stem and well formed head, and we cause no wounds that do not speedily heal.

The common practice is, to prune in autumn or spring, when the tree is divested of foliage. To this practice we make two objections. In the first place the wounds are exposed—unless covered with a suitable composition—to the searching and corroding influence of the sun, wind and rain, there being no leaves to shield, nor circulating pulp to heal them. In the second place, it causes the multiplication of succors, and often increases the evil which it is designed to cure. The sap is arrested in the spring, when its flow is greatest, in its natural course to the amputated branches, oozes out and corrodes the bark and wood, or exhausts itself in the production of a prolific growth of succors, more detrimental than the parts that have been lopped off. If pruning is performed the last of June, when the exuberant flow of sap has abated, the wounds are in a measure protected, by the foliage, from the weather; much unelaborated has become elaborated sap, and transformed into cambium, or pulp, whose healing qualities soon cover the edges of the wound; few or no succors are generated, and the heart of the tree is in a measure preserved from canker and decay. These opinions, as to the propriety of summer pruning fruit trees, have been confirmed, in our mind, by three years' practice and observation.

Another common error in pruning, is the practice of cutting all the lateral shoots from a young tree, except a few at the apex; and to cut young, vigorous wood from the tops of old trees, leaving long extended naked branches, which are often broken by the winds. In the first case, we obtain long spindling stems, incapable of supporting, when transplanted to an open situation, a respectable top. The same evil occurs in the nursery, or the forest, when the young trees stand in a crowded position. In the second case, we produce unsightly and comparatively unproductive tops. Since the offices and importance of leaves in vegetable economy have been better understood, a manifest improvement in pruning has succeeded. It is now contended, and we think upon correct principles, that none, or but very few, of the lateral branches should be cut entirely from young trees, until the tree is tall enough to form a head; but that the pruner should be content with shortening those which interfere with the main stem, and such as are of unreasonable length. By this means, we obtain a tapering, and straight stem, and retain the aid of a large portion of the leaves towards its enlargement. Every leaf contributes to the growth of the stem below the point of connexion. When the tree has attained a proper height to form the top, it is advisable, particularly with the apple, to cut out the upright shoot, leaving three, or at most four, laterals, or branches, upon different sides, to form the top. If a little attention is given annually to cutting out the small limbs, which are likely to cross or interfere with each other, the necessity of cutting off large branches will for a long time be superseded. In old trees, the old branches frequently become cankered and diseased, and young thrifty wood is thrown out at or near their base. In this case it is always preferable to cut the diseased wood, leaving the healthy shoots to fill their places. When transplanting trees, the knife should be used sparingly. If the roots are greatly diminished, in digging up the tree, the top may be lightened by thinning its branches; or if none of these can be spared without marring the form, the longer branches may be shortened, or cut in, at a bud; but we do not advise, in any case, the cutting off the entire top.

New Grains.

We have noticed in a cotemporary print, some remarks tending to discourage a prevailing propensity in our farmers, to obtain new varieties of grain. This propensity, like that for the morus multicaulis, may be carried, it is true, to a ridiculous extravagance; and although new kinds may often prove worthless, in particular locations, or in general, yet the benefits which actually result to the community, from the introduction of new varieties of grain, are palpably great, and counterbalance all the losses that accrue from ignorance of the soil or climate to which they may be peculiarly adapted. All endeavors to perpetuate the good qualities of a breed of animals, by breeding wholly from the same family, termed breeding in-and-in, have entirely failed. Even the notable example of Bakewell does not seem to form an exception to this remark: for though he succeeded for a time, his stock rapidly degenerated after his decease, unless where it was crossed with another breed. Varieties of fruits have their natural limits of extension, beyond which, we believe, human art cannot render them prolific and healthy. Why should not varieties of grain and roots be subject to the same laws which go to deteriorate animals and fruits? That they do, is evidenced by the facts, that most of the varieties which were in estimation forty years ago, have disappeared from among us, and have been replaced by those which are comparatively new. This remark will apply particularly to our potatoes and Indian corn, and in a great extent to our wheat. By change of soil and climate, the vigor of a variety may have been prolonged; but we doubt whether any variety has been cultivated forty years in the same place, without showing unequivocal evidence of deterioration and diminution of product.

We beg the reader to observe the distinction we make between species and varieties. The better to illustrate the matter to the young reader, we may state, that under the Linnæan system, plants are divided into classes, orders, genera and species. Thus wheat (Triticum) is a genus of plants, belonging to the third class (*Triandria*) and second order (*Dygenia*) to which Loudon assigns 16 species, viz. summer wheat, Lammas, Egyptian, turged, Polish, spelt, one-grained, porcupine, rushy, couch grass, bearded, rigid, crested, maize-like and long-spiked. All other wheats are mere varieties, produced, naturally or artifically, by a cross of two species, and modified, more or less, by soil and climate. It is the varieties which deteriorate, as we alledge. Varieties are multiplied wherever two species, or two varieties, are grown contiguous to each other—the pollen of one kind coming in contact with the pistil of another, invariably producing a progeny partaking of the qualities of both parents, and yet not wholly like either. Hence the strange mixture in our wheat fields, some heads ripening earlier and some later. The continued cultivation of a single variety is precisely like breeding in-and-in with a family of animals. It will deteriorate.

We will cite another illustration. Indian corn (*Zea*) belongs to the twentieth class (*Monœcia*) and third order (*Triandria*) of Linnæus. Loudon gives but two species, the common and Valparaiso cross corn; while other botanists give three or more—so that all our cultivated sorts of this grain are but varieties of probably the same species; and these varieties are continually multiplied in the way we have mentioned. When we see white kernels upon the stock of a yellow kerneled variety, caused by the impregnation of the silk by the pollen from a white kerneled stock, these white kernels are not like the white kerneled or male parent, as their appearance indicates, but they are a new variety, partaking of the quality of both parents; and if planted, this will be apparent in the progeny or product.

From the foregoing considerations—and from the well known fact, that most of the estimable varieties of grain now cultivated, are comparatively new, and have been produced from small beginnings, perhaps from a single head or stool, selected by some observing farmer or naturalist, and carefully propagated—we are decidedly of opinion, that the introduction of new varieties from abroad, and the dissemination of such as may be found deserving of notice in our country, is eminently calculated to promote the interests of agriculture, and of the community at large.

Another consideration. The prices at which these new products are held, is objected to, as savoring of extortion. In the first place, no one is obliged to buy. It is his voluntary act, and *he* should not complain; nor does he complain when he becomes a seller. In the second place, the only way to disseminate rapidly any thing which is intrinsically good, is to demand a high price for it. It will be prized and nurtured in proportion to its cost. In these matters we are apt to graduate value by the cost. We once tendered to the members of an agricultural society, a bag of choice seed, in such portions as they might choose to take, as a gratuity; and although it stood before them, and they examined and professed to admire it, not an individual took a particle. We took it home, demanded a high price, and sold it readily in a few days.

We began this article simply with the intention of acknowledging the receipt of some beautiful samples of wheat, and of returning our thanks to the gentlemen who sent them to us.

We have received from Geo. C. Thorburn samples, in straw and in grain, of the *Whitington Wheat.* It is the handsomest sample of wheat we ever saw, of any kind, although it is a spring wheat. The berry is large, plump and very white, the skin apparently thin, the head seven inches long, the straw stout and bright. Mr. Thorburn will have seed to sell in March.

We find by the (London) Farmer's Magazine of October, that the origin of this wheat was three ears selected from a field, on the mountains of Switzerland, and that it obtained a medal at the Liverpool agricultural meeting in 1836. It is also stated, in an advertisement by the way, that it grows upon poor soils, that 12 bushels sown have produced 300—and that the grower charges £8 per quarter, equal to $4.44 the bushel.

The same number of the Magazine advertises other new varieties of wheat, which are highly extolled, and which have the like recommendation of high prices, to wit, 8 guineas the quarter of 8 bushels, or 25s. sterl. equal to $5.55, the bushel. Of these we give the names of Donna Maria, Fuliard's prize wheat, or four square headed red Brittania, said to have originated from a single ear grown on the field of Waterloo, and to which was awarded the London gold prize medal. Brown's Chevalier prolific ten rowed white wheat, comes recommended by a great number of certificates of growers. This is said to produce—five pecks (about half the common seeding in England) being sown to the acre—forty-two to sixty bushels the acre. And it will be seen in the extracts we make in regard to the Yorkshire cattle show, that the Royal Standard wheat, which we take to be identical with the Whitington, is in high repute. Bating the puffing and humbuggery connected with these advertisements, and the London folks are adroit in these matters, there is no doubt, that all the above named are new and valuable varieties of wheat, which would be an accession to some districts of our country.

We have also received two beautiful samples of wheat, purporting to come from Marseilles, in France, and accompanied by a note signed W. H. Culver. One sample closely resembles the Whitington, though a shade or two darker; the other, said not to have been before imported, resembles the Italian, only that it is larger and plumper than the Italian. Both samples have the size and plumpness of the best winter wheat, though they are said to be spring varieties. They promise to become an acquisition to our husbandry.

New-York Agricultural School.

The following Circular has been addressed, personally, to a few individuals residing in different parts of the state. Relating to a matter that concerns all classes—and as many, with whom we are not personally acquainted, may feel a hearty desire to aid in this great work of industrial, mental and moral improvement—it is here addressed to the public at large—to every individual whose liberal feelings and public spirit may incline to our aid. Subscribers will undoubtedly be entitled to a preference in the advantages to be afforded by the school.

CIRCULAR.

"*Albany, November* 15, 1838.

"Sir.—In 1836, the legislature of New-York passed 'An act to incorporate the New-York State Agricultural School,' with a capital of $100,000, and liberty to increase it to $200,000—'for the purposes of instruction in literature and science, and improvement in scientific and practical agriculture and the mechanic arts.'

"The prominent provisions in the act of incorporation are—that the concerns of the company shall be managed by a board of trustees, to be annually chosen by the stockholders, of which board the Governor and Lieutenant-Governor, for the time being, shall always be members;—that the trustees 'shall purchase a farm of about five hundred acres of land, either contiguous to or near the Hudson river, and nigh to the city of Albany as shall be convenient,' and make necessary arrangements for commencing and carrying on the school. And, that the stock shall not become a matter of speculation, to the detriment of the institution—and to prevent a perversion of the school to other than its legitimate objects, the law limits the dividends upon the stock paid in, to five per cent per annum—and declares, that 'the professors, teachers and pupils of the school shall, unless prevented by sickness, or other unavoidable cause, occupy themselves at least one-half of the time the said school is in session, between the months of March and December, either in the practical agricultural business of the farm, or in the laboratory or mechanic shops connected with said school.'

"In consequence of the indisposition of one of the commissioners appointed to open books of subscription, and the death of a principal patron and manager, only about one-third of the capital stock was subscribed; the corporation was not organized, and the charter became void by non-user. At the last session of the legislature, the act of incorporation was renewed and continued in force. But the deranged state of the business concerns of the country, and the general pressure for money, has hitherto prevented any efforts being made to fill up the subscription As our commercial embarrassments have in a great measure subsided; and impressed, as we are, with a confident belief, that the projected school is calculated essentially to accelerate improvements in the great branches of productive labor, and to exert a benign influence upon society at large, we beg leave respectfully to call the public attention to the subject, with the view of carrying the provisions of the law into speedy operation.

"The law makes no appeal, it is true, to mercenary considerations; but it appeals to higher, nobler feelings—to the public spirit, to the patriotism of our citizens. Its object is to improve the moral and social condition of the state, and to augment the productions of its soil. It is designed to extend to productive labor the efficient aid of modern science, and to instruct it in what experience has taught and confirmed as the best modes of practice; and to elevate, withal, the intellectual and moral character of that numerous class of our population, who are, emphatically, the shield and strength of our freedom, to that healthful and independent condition which the safety of our country demands.

"It is unnecessary for us to dilate upon the numerous benefits which scientific and industrial schools are calculated to confer upon a community. Their great utility has been amply demonstrated in Europe, where they have been long established, and where they continue annually to increase. They seem particularly fitted for a free people, who are entrusted with the sovereign power, and who ever, while free, give the impress to national character. Should the projected school realize any thing like the benefits anticipated from it by its friends, it will become a pattern, and lead to the establishment of like institutions in our land, and to a highly salutary improvement in our industrial and social habits.

"The particular object of this circular is to apprize you of the foregoing facts, and to invite you, as a willing promoter of the public good, to take an active interest in the projected school—to subscribe to the stock yourself, and to influence the wealthy and philanthropic of your neighborhood to do the like. The shares are twenty-five dollars each. It is proposed, that when $50,000 of stock shall have been subscribed, notice shall be given in the Cultivator, Genesee Farmer, and the Albany Argus, of a meeting of the stockholders, at the Capitol in the city of Albany, to organize the Association, and at which time a payment of five dollars on each share of the stock subscribed will be required to be paid. Will you do us the favor to send your reply, before the 1st of February, addressed to Archibald McIntyre, Esq. or Jesse Buel, Albany, with a notice of any subscription you may be disposed to make, or may have been able to obtain, to the stock of 'The New-York State Agricultural School.'

"ARCH'D McINTYRE,
"J. BUEL,
"J. P. BEEKMAN."
*W. H. SEWARD,
*W. L. MARCY.

* We received permission to add these two highly respectable names to the Circular after it had been sent abroad.

Insect Enemies.

At the recent meeting of the "British Association for the advancement of Science," the Rev. F. W. Hope read a paper "On Noxious Insects occurring in the year 1838, more particularly the *Tipula tritici* of Kirby."

The author commenced his observations on the *apple blight.* In this year apple trees have chiefly suffered from the attacks of two insects; one is a beetle (*Anthonomus pomomus,*) which attacks the blossoms in bud, and prevents the fruit from what is called "setting." It is well known to entomologists, and the author hopes shortly to give its history to the world with illustrations. The second is the *Aphis,* or plant louse, which is this year exceedingly abundant. The apple, the hop, and the wheat, have suffered from it. The author would not describe these insects, as they are so well known, but made the following observations:—When vegetation in spring has made considerable advances, and the weather becomes wet and uncongenial, then *Aphides* appear in greatest abundance. He attributes the great abundance of *Aphides* this year to the cold. He was anxious to ascertain if *Aphides* are more abundant in some soils than others, and solicited information on this point. In 1829, the *Aphides* were succeeded by the *Coccinelidæ*: is this usual? The *Aphides* on the wheat this year are more abundant on the spring than the autumn sown wheat, and (near Cheltenham) more numerous on bearded wheat. *Tipula tritici* is observed to be abundant in some districts. The *pupa* and *chrysalides* are not so numerous as in former years, but the caterpillars are very abundant; but the wheat appears more damaged by Aphides than Tipulæ. The author then alluded to the kind of information wanted in these inquiries, with regard to soil, atmosphere, cultivation, and varieties of wheat, which might be supplied by the agriculturist; and regretted that there was not an agricultural section in the Association. He then hoped botanists would supply information:—1. On the species and varieties of wheat grown in this country: 2. Diseases of wheat arising from parasitic fungi and other causes: 3. The provincial and local names of the kinds of wheat. In conclusion, he suggested that a committee of the British Association, consisting of botanists, entomologists, and agriculturists, should be formed, in order to investigate the diseases incident to wheat, and other kinds of agricultural produce.

New Discovery in Philosophy.

Professor Mitchell, of Philadelphia, has succeeded in preparing an apparatus for pressing gases into a liquid and solid state. The discovery of a mode of converting gases into liquids, by compression, was first made some time ago, by M. Thilloms, of Paris. The apparatus of Prof. Mitchell is made to produce a pressure upon carbonic acid gas, of about 1,000 lbs. to the square inch, which by expelling the latent caloric, reduces the gas to a liquid, and of course creates great heat, externally, by the caloric which is thus expelled and set free. On suffering the vessel containing the liquified gas to communicate with the air, a part of the liquid is rapidly evaporated, and the rest frozen into snow, light, dry and very cold to the touch, beautifully white; and when first exposed to the atmosphere, is 122 degrees below the cold of frozen water. As rapid evaporation immediately ensues, visible in the appearance of a white vapor, and carrying off caloric, this low temperature rapidly falls to 130 or 140 degrees below zero. Mercury, which freezes at 140° below zero, becomes solid, in a few seconds, when enveloped in this snow, has the hardness of lead, and exhibits the same appearance when cut with the knife. Thus it seems, that without the all-animating principle of caloric, which exists, either in a latent or free state, in every thing, all gases and liquids would become solids, and every organized being, animal and vegetable, would cease to exist. How wonderful are the works of the creation!

This discovery promises to become of great use in science, in the arts, and even for domestic purposes. Prof. Mitchell is engaged in a course of experiments, with his apparatus, the results of which will be made public through the Journal of the Franklin Institute.

The Farmer's Garden.

KITCHEN DEPARTMENT—(*Continued.*)

25. Hop.—Hops are deemed indispensable, with many good housewives, in the making of yeast, or beer, or both. A few roots, planted on the outer border of the garden, will require little other care than polling and picking them, and from six to ten poles will supply the wants of the family.

26. Horse-radish.—This is a valuable and wholesome condiment, or sauce, with meats. It grows from cuttings of the root, as well as from tops. To have fine roots, it should be planted deep, in rich mellow ground, and stand two years. For winter use, it may be taken up in the fall, and packed in the cellar in earth, like other roots. A few feet of ground will suffice for its culture, and to this it should be confined.

27. Hysop is a sort of shrub, the flower spikes of which are used, fresh or dried, for medicinal purposes. Half a dozen plants on a border will suffice.

28. Lettuce is common in our gardens, and constitutes the principal sallad for our tables. There are a great many varieties, and there is a material difference in their quality. To have fine heads, it is necessary to sow in September, to protect the plants in winter, and transplant in May. The curled Siberian is in general esteem. If sown in a hot bed, and carefully transplanted, about the first of May, into a rich east or west border, the coss and some other

kinds will make tolerable heads, and be excellent.—The leaves may be gathered and tied, as directed for endive, with great advantage to their quality. Lettuce may be sown very early, and small sowings may be made, at intervals, till midsummer.

29. Marjoram.—There is an annual and a perennial—the latter generally cultivated here, as a sweet herb. It should be sown early, cut before it is out of bloom, and hung up in little bundles to dry for winter use.

30. Melons.—In northern latitudes we recommend the treatment, both for water and muskmelons, which we suggested for early cucumbers; that is, burying under each hill a half barrow full or more of hot dung. The melon is sensitive to cold and to moisture—the hot dung imparts heat and induces dryness. If the melons can have the benefit of boxes, covered with glass, through June, these will greatly facilitate their growth, as well as protect them from the striped bug. Our boxes, which have been several years in use, are 18 inches square, six inches deep in rear, and four in front, and are covered with a moveable sash, containing six 6 by 8 panes of glass. Both the water and muskmelon like a sandy dry soil. The hills should be planted six feet apart at least, and not more than four plants should be left to grow in a hill. The old species of muskmelon are far inferior to many new varieties, as the citron, pine apple, cantaloupe, &c. When you get a good kind, save your own seed, and plant no other variety with it.

31. Mint.—The spearmint is often used in seasonings and salads—the peppermint for distillation and medical purposes. A few roots of each are desirable in the garden.

32. Mustard.—The leaves of the white kind are used in salads with pepper grass. The black seeded is used for greens, and is cultivated for the seed, to be manufactured for table use. When intended for seed, it should be sown in rows, two feet apart, early in the spring, and the plants thinned to four or five inches apart. It will ripen in July. Every farmer may raise his own mustard for the table, and manufacture it too; and though not so comely in appearance, it will prove, in eating, much superior to much that is imported from Europe. We have seen it powdered by rolling a junk bottle over it upon a polished stone or hard board. But we have manufacturers who pay a liberal price for the seed, particularly in our cities.

33. Nasturtium.—This is an annual, with a handsome flower, whose berries, preserved in vinegar, are an excellent substitute for West-India caper sauce. Sow early in May. The vines may be supported by brush laid upon the ground.

34. Onion.—This is a vegetable that every farmer can raise, and should raise. It serves many purposes in kitchen economy, and is healthful, and generally grateful to the palate. The onion is sown here about the 25th April, in drills one foot apart, the ground being rich and well pulverized. The plants are ordinarily thinned to the distance of three or four inches; though if two to four are left together, they often bottom well, and grow to a sufficient size. The tree or top onion, may be planted in September; a slight covering of straw will protect it during winter, and it then comes into early eating in the spring. The common sorts are also sown and preserved through the winter in this way. Some people break down the tops in July, to increase the bottoms. This practice may facilitate the maturity of the crop, though it does not increase it. The best way we know of, of preserving onions for family use, is, after they have been pulled and dried upon the ground, to take a stick, of two inches in diameter, six to ten feet long, split it through the centre into two or four parts, to within one foot of the but; then to begin at the bottom and draw the tops of the onions through the slits, letting them close as you progress, till you have reached the top, when the whole is made fast with a stout cord. In this way the onions are kept dry, and will not grow, and occupy but a small space. The onion gives from two to five hundred bushels the acre, and we have known the product greatly to exceed the latter. Some tread the ground, after the seed is planted, and then give it a slight raking, to render it smooth and even. The crop should be drawn when the collar, or lower part of the stem, shrivels and dries. They should be thoroughly dried, before they are housed for winter.—Sometimes the onion is planted in hills, four or five seeds being dropped in each hills, with intervals of five or six inches between them, and in this way they often do well. Another mode of raising the onion, and we believe it the prevailing one in the middle and southern states, is to sow in June, in drills six inches apart, and thick. They will form small bottoms, about the size of a filbert, the first season. They are then planted out the following spring for a crop.

35. Parsley.—This seeds the second year, and is therefore a biennial. Sow in drills at eight inches, in May, or later. A bed four feet square will supply a family. To have it for use in winter, it may be sown in any vessel filled with earth, and kept in the kitchen.

36. Parsnip.—This root requires the same cultivation and tillage as the carrot. It should be gathered late, as it continues to improve in flavor even till spring, till which time the main crop is permitted generally to stand in the ground, unless wanted for winter market or use. When put in the cellar in autumn, the roots, like those of the carrot and beet, should be covered with earth.

37. Pea.—This is a favorite with almost every one, and every one may enjoy it, who has a garden, with but little labor. The first crop may be sown as soon as the frost is out of the ground, and the surface sufficiently dry, and the sowings may be continued at intervals to the first of August. The early sorts, most cultivated, are the June, early Charlton, Bishop's dwarf, &c.; the later ones, marrowfats, Knights, &c. &c. Plant in double drills one foot apart, with intervals between the double drills of two to four feet, according to the growth of the pea.

38. Potato.—For early use, a few hills may be planted in the garden; and these should be of an early variety. The tubers or sets may be mixed with earth in a vessel, and set in the kitchen, or slightly covered in a hot-bed, and afterwards planted; and this will cultiate their maturity.

39. Potato, (sweet,) may be raised here in favorable seasons; though they seldom acquire the rich flavor that distinguishes them at the south. To cultivate them here, make a bed of hot dung in May, of one to two feet thick, and a yard square, cover the dung with four or five inches of good mould, on which lay the seed, and cover it with as much more earth. The heat of the dung will soon cause the potato to grow, and when the plants are of the size of cabbage plants, they may be drawn, and planted out with the dibble like cabbages, in hills four feet apart, or the plants eight inches apart in ridges. The soil should be sandy and dry, and the earth should be gathered into cones or ridges, as for melons. The quality of these potatoes is improved, by exposing them some days after they are dug, to the ameliorating influence of the sun's rays. They can not be well preserved long in this latitude.

40. Purslane, a vexatious weed, which Cobbett says Frenchmen and pigs eat raw, when they can get nothing else. It however makes a very good pot green, when boiled.

41. Radish—several varieties. Sow very early, and at intervals, in drills eight inches apart, and thin to two or three inches between the plants. The early purple top and turnip rooted succeed best for early crops. The black Spanish may be sown in July with fall turnips, and used through the winter and spring.

42. Rhubarb.—This is an excellent article, and should be in every garden. It is perennial, and resembles the burdock much in its growth. The stock of the leaf, which is large and tender, is in high esteem for tarts and pies, and in this way the plant is believed to be highly conducive to health. Peel the stocks, cut them into half inch length, and put them into tarts, pies or puddings, just as you would green gooseberries or currants. Give the plants two square feet each, in good ground, and a dozen of them will supply a family from May to August. The rhubarb may be propagated by offsetts, or from seed, which ripens at midsummer, and may be sown as soon as gathered. There are several varieties. This is getting into great demand as a market vegetable. The seed stocks should be cut in, except one or more left to produce seed.

43. Rue is a handsome little shrub, of occasional use in the family. Two or three plants are enough.

44. Sage, is much employed in seasonings and stuffings, and is sometimes used for tea. It is propagated by seed and by slips. Sow in May, in drills, and transplant the second year, leaving intervals of eight to twelve inches between the plants. Cut the tops before they come into bloom, and dry for winter use.

45. Salsafy, or vegetable oyster, very much resembles the parsnip, in its root, in its hardiness, its culture, and in its properties and manner of cooking for the table. Enough should be gathered in autumn for winter use.

46. Spinach.—There are two kinds, both excellent pot-herbs, one of which should be sown early in September, for early spring use; and the other early in the spring. Sow either broadcast, or in drills, and cover the bed of the winter sort, in November, slightly, with straw or coarse litter, and keep it on till the breaking up of frost, when you may begin to use the crop.

47. Squash.—There are many varieties, both for summer and winter use; and they are continually multiplying by cross impregnation. For summer varieties, those termed bush, which do not send out vines, are to be preferred. The best winter varieties, for garden culture, are the crook-neck, Valparaiso, under most of its modifications, and vegetable marrow. The only caution necessary in the culture of squashes is, that the hills be at least six feet apart, and that but two plants of the winter varieties be left to grow in a hill. To preserve the squash in winter, give it a cool, and particularly a dry berth, where it will be protected from the frost.

48. Tansy.—A perennial medicinal herb, worth having. A single root will soon generate a supply.

46. Tomato.—There has been, of late, so much said in commendation of this vegetable, as promotive of health, that *we* need not recommend its culture. It is a grateful and healthy vegetable, in many ways, to those who become accustomed to its use. To have it in season, during the summer heats, the seed should be sown in a hot-bed, like cabbages, from which the plants may be transferred when the season will admit of it. They are an excellent ingredient in soups, make a good catsup, stewed in their own liquor they are a fine sauce with meats; they may be dried or pickled; and they are made the basis of a medicine, which, if we are to credit the declarations of the venders, is an infallible cure for most all sorts of diseases which man is heir to.

50. Turnip.—None but the early sorts are usually cultivated in the garden, and these seldom escape the depredations of the fly, either in the top or root. They may be sown very early, and at all subsequent periods, before the first of August; yet those designed for winter use, and for farm stock, are generally cultivated upon the farm.

51. Wormwood is an herb purely medicinal; yet as almost every family has an occasional use for it, no one should be without a root or two of it in his garden.

We have thus given the names of fifty vegetables, exclusive of what are termed fruits, which may be usefully cultivated in the farmer's garden, and which are all valuable as articles of diet, as wholesome condiments, or for their medicinal properties—and which require no great skill in their culture. Each man can select from the list such as suit his taste, his wants, or his garden grounds. We know it will be objected by some, that the care of the garden requires too great an expense of labor, and that it will not repay, in its products, for its cost. In reply to this objection we would remark, that the master, and the unproductive inmates of the family, may perform most of the labor, and find in it a recreation, when they are not engaged in more useful employments; that there are always intervals, in the business of the farm, when farm laborers may be profitably employed in the garden; that, when a market is contiguous, for the sale of its surplus products, garden culture has been found to be the most profitable of any description of rural labor; and finally, that every man may limit his garden to the space which he is conscious he can cultivate to advantage. We toil for wealth, not to carry it with us to another world, but to purchase and enjoy the comforts and rational indulgencies which belong to this. Let us then act accordingly, and avail ourselves of those blessings which a kind Providence has placed at our hands, for our benefit and use.

We shall next treat of the ornamental department of the garden.

New Mode of applying Lime.

We observe, in the Farmers' Cabinet, a communication from E. Tatnall, describing the mode in which he had successfully applied lime to his corn crop. He applies it with manure, and yet so as that the dung and lime do not come in contact. His practice is to apply, late in the fall, 25 ox-cart loads of manure to the acre, spread it evenly, plough the ground, and harrow it well, in the fall. In the spring following, he applies 60 bushels of lime to the acre, and again harrows until the ground is in good order for planting. In the culture of the corn, he takes care not to disturb the manure buried by the plough, preferring that it should decompose without exposure to the sun and rain. After the corn is taken off, he ploughs deep, so as to mix the manure with the earth, sows broadcast, and harrows in wheat. In this way he raises 60 to 70 bushels of corn, and 25 to 30 bushels of wheat, upon an ordinary soil. By ploughing for corn in the fall, Mr. T. thinks he destroys the cut-worm, as he is never troubled with it. We think it more likely that the worm is destroyed by the caustic lime which is applied in the spring.

Whether the lime contributes to increase the corn crop or not, we have some doubt; though as a carbonate, we have no doubt it improves the mechanical texture of the soil, and benefits the wheat. The dressing of manure is a heavy one, and should of itself, in our mode of planting, and if unfermented, give the crop of corn obtained by Mr. Tatnall. The manure had, however, been probably fermented, and the distance of planting, in Pennsylvania, is greater than it is with us. The mode of applying the lime, to the same crop, and yet not coming in contact with the manure, we think a decided improvement.

The utility of lime was, however, strikingly shown in another experiment of Mr. Tatnall. He applied it, in different proportions, from 60 to 100 bushels the acre, to eleven acres of very poor land, without any manure, and sowed with oats. The crop was unusually heavy; and best where the most lime was applied.

Tropical Plant Company.

Dr. H. Perrine, who was formerly American Consul at Campeachy, has been for some years assiduously engaged, and has spent much time and money, in forming an establishment near Cape Florida, for the introduction and propagation of tropical plants, the culture of which promises important national, as well as individual, advantages. The government of Florida, has passed an act to incorporate the Tropical Plant Company; and Congress has made an appropriation of a township of land to Doctor Perrine and his associates, on certain conditions, to aid in promoting the object of the association. The Doctor has already a large collection of plants at Indian Key, contiguous to the coast, is about removing thither with his family, and now invites emigrants to join him, and capitalists to embark in the enterprise.—We subjoin Dr. Perrine's note,

"TO THE FRIENDS OF THE ENTERPRISE.

"The principal objects of the company, are to form a nursery of supply and a model of cultivation of the valuable plants of the tropics.

"As however, while Indian hostilities continue, it will be impossible to pursue with safety their intended labors on the main land, of tropical Florida, the trustees will delay the organization of the company, and will apply their personal resources to the formation of a preparatory nursery at Indian Key, and the adjacent inlets. The superintendant Dr. Perrine, will hence reside with his family at Indian Key, until the cessation of the Seminole war, where he will continue to accumulate all the seeds, plants, and other elements for the permanent nursery, to be then established on the southern coast of the Peninsula. During this important interval, the most *essential aid* to these preparatory labors may be *immediately afforded* by very *easy means* in the power of many philanthropic friends of this patriotic enterprise,

"1st. By transmitting to Indian Key, at least two seeds or cuttings, &c. of every superior variety of every valuable vegetable which the possessor may consider adapted to the climate and soils of tropical Florida.

"2. By transmitting a detailed list of all books which the owner may deem necessary to enter into a Botanical and Vegecultural Library, especially adapted to the tropical climate and productions of south Florida.

"3. By transmitting a letter containing the desires of the writer in respect to the purchase of one or more shares of stock, in the Tropical Plant Company.

"The trustees do not expect to receive any articles or services without returning an ample equivalent. All letters should be addressed to Charles Howe, postmaster, at Indian Key, south Florida, the financial trustee. All packages of seeds, &c. not exceeding two ounces, should be directed to the Patent office at Washington, whence they will be forwarded to Indian Key. The proprietors of green houses, &c. will render themselves especial services by sending their respective mites during the ensuing six months.

"Even the druggists may contribute the valuable seeds, occasionally found among their tropical medicines. The trustees are James Webb, Judge of the district at Key West; Charles Howe, Inspector of the port at Indian Key; and Doctor H. Perrine, late American Consul at Campeachy.

"*New-York, October 15th, 1838.*"

The Robinson Fund.

We are happy of the opportunity of being authorized to add $20 to this fund, designed to be awarded in premiums for certain agricultural books—by Prof. F. H. Gordon, of Clinton College, Ten.—for whose communication, inserted in another column, we bespeak an attentive perusal. Whose name shall we add next?

The American Institute,

Held its eleventh anniversary in October. The articles exhibited exceeded in number, variety and excellence, those shown at any former exhibition.—The receipts for admission were greater, by $2000, than those taken at the last fair. Two hundred medals were awarded as prizes, exclusive of several hundred honorary diplomas—a list of the prize articles, and the names of their owners, together with the very able address of Mr. Davis, of Massachusetts, delivered during the fair, are given at large in the Journal of the Institute, a monthly publication which we again recommend to the patronage of the American public, and particularly to the mechanic and manufacturer. The permanency of the Institute is now put beyond doubt, and the benefits which it is conferring on the country are palpable and wonderful.

We subjoin two extracts from the excellent address of Mr. Davis—one giving a happy illustration of the dependance of agriculture, manufactures and commerce upon each other; and the other pointing to the advantages which result from the diffusion of useful knowledge—of moral and intellectual culture. The address does great credit to Mr. Davis and to his country—and evinces in him talents of a high order, and sound American principles. It cannot be read without interest and profit by any one who has the good of his country—of his *whole* country—at heart.

EXTRACTS.

"We have lived in vain, if we have not discovered that the arts and commerce must unite with agriculture to supply the necessary demands of civilized society. It is but the natural division into which labor arranges itself, to feed and clothe us.

"The agriculturist produces from the earth—the manufacturer converts productions into forms fit for use, and the commercial class distribute the commodities of producers where they are required for consumption.

"If Divine Providence had supplied necessities in such a manner as not to require labor, we might dispense with it; or if the earth produced in a form suited to our use, we should only be under the necessity of cultivating, and might abandon manufacturing; and if it yielded the same productions at all places, we might abandon commerce. But we must till the earth or starve; convert the cotton, the wool and the flax into cloth, or go naked; dig the ore from the mountains, and convert it into iron, or cease to have tools, and whatever is made with them; and must interchange the products of different climates, or cease to enjoy them.

"This division of labor is so essential to civilized man, that whenever we abandon it we must return to barbarism. For converting wheat into flour, and wool into cloth, is quite as important as growing them."

"A knowledge of the properties of bodies, saves the slow and tedious process of experiment, which often, for the want of such knowledge, leads to dissappointment. If the agriculturist understands the elements of plants and soils, he readily discovers their adaptation, and can supply in soils those deficiencies which often defeat the labor of the unconscious husbandman, or he can give such direction to it as to render it successful. The arts rest upon principles very often but imperfectly understood by the workman; but the better he comprehends them, the more easily he detects and avoids obstacles, and attains to successful results. As a knowledge of the chemical affinities and union of bodies is of the utmost importance to the dyer, the painter, the tanner, the printer, &c. who thereby understands the rationale of his process, so is a knowledge of the mechanical powers no less important to those engaged in the use or construction of works where those powers are employed.

"Our country has been much distinguished for the invention of useful compositions and labor saving machinery; and may it not be chiefly imputed to the fact, that useful knowledge is not only largely diffused among all people, but the avenues to it are open, and most men, who have a taste for it, find no difficulty in indulging in it?

"Moral and intellectual culture is an essential element of free government; and it is difficult to comprehend how its character can be understood, or it can be maintained by the elective franchise, without it.

"In private life it opens new resources, gives a stronger and better directed impulse to our efforts, and fills the mind with higher, more just, and confident hopes of success.

"But above all, it brings us out of darkness into light—elevates us from slavery to freedom—transfers our tastes and pursuits from the arts of violence to those of peace—and creates that vigorous prosperity, that animated zeal and happiness, which have spread over this broad country, and which have allured from their homes, from the tender ties of blood, and the graves of their fathers, emigrants from all parts of Europe."

Moral Culture,

It is now urged, by a hundred pens, is indispensable to the formation of good citizens; and it is a branch of education, that all agree, has been greatly neglected in training up the youth of our country.—There is not a better antidote to vicious habits, and immoral conduct, in youth or manhood, than steady attention to useful business. Indolence is the parent of vice, all the world say, even, in many cases where the mind has been trained to moral culture. It is easier to prevent, than to cure, moral, as it is physical diseases. If these propositions be correct, then industrial schools would tend greatly to aid moral instruction, if it did not in fact inculcate it. Idleness being the parent of mischief, we should seek to prevent it, by extending to labor those aids which would enlighten and elevate it in the scale of society—which would render it independent and desirable. Young men, carefully educated in the practice of husbandry, or any other useful employment, and so instructed, at the same time, in the philosophical principles of their business, as to feel a reasonable hope of becoming respectable and useful in its pursuit, would be the last to indulge in immoral habits, or to eat the bread of idleness; they would feel animated by the strongest inducements to become examples of industry and virtue—they would love their business in proportion as they became acquainted with its principles, and as it promised, the certain means of rendering them intelligent, independent and useful. Many persons are idle, and often consequently vicious, because they were never taught to labor, and know not the proud glow of independence which one feels who can say, on scanning his means and the enjoyments they yield him—"All these are the fruits of my industry.—Thanks be to God, that I have been thus enabled to provide for myself and to help others." We become attached to good habits, as well as to bad ones, if we put them on in youth. Thus we see men who have been inured to industry, clinging to it, as to a companion of youth, after the inducement to practise it, and not unfrequently the ability to perform, have ceased. And we see many, very many, as strongly attached to habits of idleness, with its concomitant evils, because they were wedded to it in early life, though want and dishonor stare them in the face.

We all know the happy influence of houses of refuge, in reforming juvenile offenders by moral discipline, and *instruction in a business by which they can earn an honest livelihood, and render themselves respectable in society*—considerations which perhaps never entered their minds till they became inmates of these moral and industrial schools. If then habits of industry will *reform* and *reclaim* those who have been vicious, we have the strongest reason to believe, that they will be equally efficacious in *preventing* the formation of bad habits. We therefore say, if you would raise the moral tone of society, teach your youth to labor and to think—teach them to provide honestly and abundantly for themselves, by giving them early habits of industry, and few of them will ever become tenants of a jail or a poor-house.

"What can the Legislature do to improve Agriculture?"

This question was propounded by a commercial convention lately convened at Richmond, Va. to a committee, who were directed to answer it by report. A report was made by Mr. Ruffin, editor of the Farmers' Register, from which we make the following extract.

"In reply to the inquiry, 'what can the legislature do to improve agriculture?' your committee will merely state, in general terms, that every means will be useful and profitable by which light and knowledge will be diffused, and no other action, no other aid or boon is desirable, or would be beneficial. There are so many valuable modes of diffusing agricultural knowledge, that the difficulty is not to find, but to choose among them. Boards of agriculture, agricultural societies, and premiums upon a judicious plan, agricultural schools and experimental farms, and agricultural publications, each and all, elsewhere, have worked admirably to forward the great end in view. But if no more were done at first, by legislation, than the institution of a board of agriculture, as merely an investigating, consulting, and advising body, incalculable benefit might be expected to grow out of one and a cheap mode. Such a board (if the system of furnishing aid should go no further) might be limited in annual expense to $1500, or barely more than the general assembly has spent, year after year, merely in the time used for electing an individual to execute the mechanical business of printing the journals and documents—less than the expense in time and money caused by each single elaborate speech dilivered in that body upon federal relations—not one fourth part of the annual expense of the geological survey, and perhaps not one hundreth part of the money wasted in every session in useless, or worse than useless, debate."

The report closes with a resolution, "that the commercial and general interests of Virginia and North Carolina, as well as the peculiar interest of the agricultural class, require that legislative aid should be given, promptly and effectually, to the diffusion of agricultural instruction and knowledge, and to the promotion of agricultural improvement."

The Mulberry.

We stood alone, among our cotemporaries of the press, for a long time, in maintaining, that the morus multicaulis was too tender to withstand our northern winters. We see our opinion now confirmed by some of the longest established growers, who, if we remember right, once maintained a contrary opinion. And we notice in a late Farmer and Gardener, printed at Baltimore, Md. "directions for preserving the multicaulis through the winter,"—which consists in *taking them from the ground*, and covering them with earth in the cellar. At a late farmers' meeting in Northampton, Dr. Stebbins and Mr. Whitmarsh, who have both, we believe, for a number of years, been actively engaged in propagating and vending the mulberry, pronounced the multicaulis not suitable for our climate. We subjoin quotations from the remarks of each.

"Experience has taught us," says Dr. Stebbins, "that our climate is not congenial to the habits of the morus multicaulis plant; many thousands have been lost every year in consequence of not providing a shelter and protection for them against the frosts of autumn, and the severe cold of our winters. It has been demonstrated to us by expensive experiment, that the tree is not suited to our borean seasons."

"The principal objections to this tree is," remarks Mr. Whitmarsh, "that the leaves contain a great proportion of watery matter, which causes the worms that are fed upon them to be unhealthy, and hence injure their silk. He thought this objection would operate more seriously at the south, where the seasons are longer and warmer. The heat would cause them to grow more rapidly, the leaves would be larger, and he thought, imbibe more moisture. He regretted the universal adoption of this tree at the south, and feared that a failure caused by this fact, would retard the progress of the [silk] business ten years, by discouraging so many who would become losers."

We quote the above as affording hints that may be useful to those who are about embarking in the silk business; though we somewhat doubt if Mr. W. is correct in his objections to the leaves of the multicaulis, and we think he is decidedly in error in supposing that this objection, if well founded, will be greater at the south than in the north—the greater heat at the south decreasing, instead of increasing, the succulence or watery properties of the foliage.

These two gentlemen give a decided preference to what they term the *Alpine*, which Mr. W. says is "the kind universally used in France and Italy." We do not mean to charge these gentlemen with wanton deception, for we have a high opinion of their good standing; yet there is something so mystical in these declarations—so contrary to received opinions—that we can not pass them as current truths, without asking for some further explanation. We have examined all the botanical and other works in our possession which treat of the mulberry, and they are neither few nor of doubtful authority—and yet we can not find in any one the term *Alpine* given to any species or variety of the mulberry. And as to the assertion that the Alpine is universally used in France and Italy, we have Gen. Tallmadge's declaration, that in Finizio's establishment, in Italy, which he visited, 3,000 lbs. of sewing silk are made a week, mostly from the black mulberry (*M. nigra;*) that Finizio stated to him, that the worm fed on the black mulberry made the strongest thread; that on the white mulberry finer and better fabrics; that on the Chinese (*M. multicaulis*) still finer and more delicate fabrics. And we think, (for we have not the letter at hand,) that Gen. Tallmadge says the white mulberry (*M. alba*) is almost exclusively employed in France. Loudon says, "the M. alba is commonly cultivated in France and other countries, for its leaves, to feed silk-worms, though in some parts of Spain and Persia they are said to prefer the black mulberry."—*Enc. Plants*, 782. The Alpine, we presume is a *variety* of the M. alba, and is probably the one alluded to by Loudon, where he says—"the most valuable variety of the M. alba is one grown in Italy, and especially in Lombardy, with vigorous shoots, and much larger leaves than the other." This may also be the Dandolo of Loudon, and the Italian of Sweet, and possibly the Brussa of Asia, from whence it may have been brought to Italy.

Dr. Stebbins advertises the public, that the undernamed (and many not named) descriptions of the mulberry, may be had of him in Northampton, viz. the Manilla multicaulis, the Canton, the *Alpine*, the *Asiatic*, the *Smyrna*, the Brussa and Dandolo. Now we protest against this fabrication of new names, for old things, whether it be from ignorance, for novelty, or to subserve the interests of the trade. Those printed in Italics appear to us to be absolutely of new coinage. This unnecessary multiplication of names tends to mystify the business, to deceive the public and to retard a useful branch of national industry. We believe that all which are named in the Doctor's advertisement are merely *varieties* of the white mulberry, differing somewhat in the size of their foliage, and in their hardihood, but very little in their properties for silk.

We have no sort of objection that Doctor S. should puff his own wares, or his own kind of trees—but we do object to his doing it to the prejudice of others, and of truth—which he indirectly does when he remarks—"The Brussa and Dandolo appear to be selected white mulberry—leaf not large—tree hardy, and there are some other varieties, *which may be used for change of food!*" Now if the Doctor has seen the cocoons and silk produced *exclusively* from the Brussa, he must know that the insinuation here made, that it is unfit for the *entire* subsistence of the silk-worm, and the production of excellent silk, is neither ingenuous nor true; and if he has not this personal knowledge, he has no right, as an honorable man, to give the intimation imputed to him.

The general impression is, that the M. multicaulis will produce few or no seeds. This is probably owing to its rapid and continued growth of wood—and the tree will probably fruit freely when it has attained to maturity of growth. We have yet none but young trees among us, comparatively; and it is particularly remarked of the mulberry, that young trees are shy in bearing, and that the quantity and size of the fruit increases as the tree advances to maturity.

In the East Indies, according to Loudon, the plants are raised from cuttings, eight or ten of which are planted together in one pit, and the pits are distributed over the field at the distance of two or three feet every way. These cuttings being made firm at the lower ends, soon form stools about the size of a raspberry bush, and from these the leaves are gathered. The stools are cut over once a year to encourage the production of vigorous shoots from the roots.

Spirit of Agricultural Improvement in England.

The spirit of agricultural improvement seems to have been awakened in England in an eminent degree, and a zeal to pervade all classes, particularly those of the higher orders, to give to this primary branch of labor, every stimulus and encouragement to improvement, as the great business which constitutes the basis of national prosperity and greatness. Not only has a national society been organized during the last year, but several county societies have gone into operation, under the most flattering prospects of usefulness. We make some extracts below, from the proceedings of the Yorkshire society, at their first annual show, as well to show the spirit that prevails there, as that our readers may profit by the information and suggestions which they contain. After the exhibition had closed, which was remarkable for the great number of fine animals, and new and useful implements of husbandry, which were shown, twelve hundred persons sat down to dinner, which being finished, and the health of the royal family drank—the Chairman, Earl Spencer, rose to explain the objects of the society.

"This being the first dinner of the Yorkshire Agricultural Society," he remarked, "I feel that it is my duty to call your attention to the objects we had in view in establishing this society. Those objects are, to promote agriculture in all its different branches—to render the cultivation of the soil, and the breeding of stock, as improved as the present knowledge of the country can make it—what I mean by improvement in agriculture and good farming is, to cause the greatest amount of produce at the least possible expense. It is not that we wish to encourage farmers in extravagant expenses to make their farms like gardens, when that will not answer the purpose of their pockets—but to employ their capital judiciously, so as to improve the land, and obtain as large a return as they can for the money they lay out. On this, the first occasion of our meeting, we have had a good exhibition of stock, and now, I am happy to say, a full attendance of members. The exhibition we have had to-day, I need not tell you, is admirable as to the quality of the animals shown, and the number was very great indeed. But the object of this meeting is not merely the exhibition of stock; it is collecting together a body of the farmers of England, in order that they may, by communicating with one another, and by what they see and hear, improve themselves in the profession in which they are engaged. When I address this large assembly, in this I also can say, that we have been successful. It is not necessary for me to tell you what the advantages are of improving the breed of cattle. I do not recommend to farmers of small capital to attempt to buy females of great value, and lay out large sums to produce male animals for the benefit of others; because nothing is more essential in farming than that a man should consider the capital he has, before he engages in any undertaking; but it is for persons of large capital to endeavor, by taking pains themselves, to produce male animals, fit to improve the different breeds of domestic cattle in this country. These exhibitions are of the greatest advantage, not merely to persons of the class I have described, but to all farmers whatever. Although I would not recommend any extravagant expenses, depend upon it, if you be careful in the selection of your male animals, you will, even with more moderate females, farm to greater profit. This society also seeks to improve the cultivation of land. I need not tell such a meeting as I am now addressing, that the throwing away manure upon the growth of weeds is not a profitable way of farming; that leaving land undrained and growing rushes instead of grasses, is not good farming; that getting out the heart, by neglecting land, and not applying a proper degree of cultivation is unprofitable—because, depend upon it, that money laid out in improving is the money that will come the quickest back again into your own pockets. With this view, the society has given premiums for the best cultivated farms. By so doing, I am quite sure, we are not only giving those good farmers new information, but we are encouraging them in doing their best. Besides those, we have given prizes for publications on agricultural subjects. It is our intention that each member shall receive a copy of the prize essays gratis, on applying to the secretary. I have stated the objects of this society, and the modes by which we intend to promote it—our object is to produce the food of man in the cheapest manner in which food can be produced. I think the society deserves the support of not merely landlords and farmers, and those connected with agriculture, and the value of land, but also of the commercial and manufacturing classes of the country; it is also good for the laborers of the country; in short, a society which has for its professed object, food at the cheapest rate, is good for every one who eats."

P. B. Thompson—"One of the first objects of these meetings, in addition to what had been so ably stated by his noble friend, was to keep up an open, unreserved communication, between gentlemen and farmers, which he trusted that meeting would promote to the utmost of their power. It was not by speeches, but by plain, honest, unreserved conversation, that he thought these meetings ought to be sustained; and if any person knew any thing more than his neighbor, he was bound to state it. Well, then, yesterday morning, he received a parcel of wheat from Berkshire, which he thought likely to be serviceable if grown in this country. It was found three years ago, growing on the mountains of Switzerland; since then it had been grown in England, and the sample he produced was grown in Berkshire. It was sown on the first of February, called Royal Standard wheat, the crop had now (29th Aug.) been reaped a fortnight, and was supposed to be at least seven quarters [56 bushels] the acre. Another subject worthy their attention was the application and formation of manure with the least possible waste; next year he hoped to be able to give them some useful information upon that point. He never enjoyed a greater pleasure than in witnessing the cattle that day. He never looked over so good an exhibition of female stock as he had witnessed that day—indeed 200 guineas [$932] had been offered for one of the cows shown. That was a practical proof of his noble friend's observation, that the money came back again to the farmer's pocket."

J. W. Childers, Esq. M. P.—"He believed that an exhibition such as he had that day witnessed, had scarcely ever before been seen in England. But he thought that only a beginning, when he saw that within a month or two, the society had doubled the number of its subscribers, he felt that the society would go on increasing from year to year, until its extent was only equalled by the Highland Society, on the model of which it was formed. The Highland Society numbered 3,000 members, and seeing that they had reached 800, he had very little doubt but they would also reach 3,000." Mr. Childers said he was about to propose as a toast—"the cultivator of the best farm"—and proceeded to say—"he trusted in time that every farm in Yorkshire would be raised to the state of this prize farm. He believed it was considered almost a garden, being in such fine condition, and he saw no reason why the county should not teem with farms of this description. What was it that gave this farm such a superiority? its soil was naturally good, but so was the soil of a great deal more land in Yorkshire—it was science and capital, united, that gave those fertile and beneficial results."

"W. R. C. Stansfield, Esq. M. P.—proposed the health of Mr. James Roberts, the tenant who, within the last five years, had drained, in the most effectual, judicious and economical manner, the largest quantity of land in proportion to his occupation. He had the greatest satisfaction in calling their attention to what he conceived was one of the most important branches of the society's operations—drainage he considered the foundation of every thing. Unless they had the means of preparing the soil for the manure and seed all was wasted. He feared this subject was but little considered, either in England or Scotland; if he took his own neighborhood as an example, a mountainous country, with a numerous and very industrious population, the means of improvement by draining had scarcely begun. Without draining, land was unfit for turnips or seed husbandry—it was unfit for human occupation."

Mr. Bates, a successful competitor, on his health being drank, made a handsome acknowledgment. He drew a contrast between the condition of the cattle now and fifty years ago; and proceeded to say, that

"The interests of agriculture he considered of permanent national importance; it was a science to which chemistry and all other branches of natural philosophy ought to give place. He alluded to the proposal for introducing a section of agriculture in the British Association, and regretted that there was not a Professor of Agriculture in either of the universities."

E. S. Caley, Esq. M. P.—"Thus it was, that as science advanced, agricultural operations were carried on with ten times more advantage than before, merely, because, instead of the observations of one man, or two men, they had now the result of the combined operations of all the world. That was the reason why he anticipated the greatest advantages from meetings like that. They were all brought together, not merely to look at the fat stock, as Earl Spencer had observed, but to join in harmony, to impart the result of their own observations, and to receive information from the experience of others; and as it is well known that two heads are better than one, they were much more likely to draw true, faithful and profitable conclusions, as related to agricultural operations, by meeting there and comparing their different conclusions, than they would be if they were all to stay at home and say nothing. He did not say they could not learn anything by staying at home; but, at all events, they could not learn what their neighbors were doing. There was an old saying prevalent in the world, about an old country woman, who had never been from home in her life, but on the occasion of her young mistress being married, was prevailed on to go to the next village to see the festivities, and on getting to the top of the hill, she said—'Lord hey massy on us! wheeaivver thowt t'world was hoaf see big as this!' He mentioned this to illustrate the advantages of not staying at home, in order, not merely to learn from others, but to communicate to others what they knew themselves. He would say to them—'freely ye have received, freely give.' It was not merely for the love of gain they were assembled together on that occasion, or that they cultivated the noble science to which they were addicted; it was not merely for the sake of gain, but for the pleasure of breeding the best ox, or cultivating the best farm. There was something beyond this, some better feeling in their nature to gratify, than the mere love of gain. Was it not a manly, an honorable satisfaction,—what was called in Yorkshire 'a bit of pride,' to show the best sheep or ox to their neighbors. It was not merely the love of gain, but the love of approbation. It was a pleasure to their hearts to look round their own farm-yards, and see to what perfection things might be brought, what symmetry their forms might be made to exhibit. It was not merely the love of gain, but the love of beauty, and the love of praise from their neighbors, who were alike gratified in affording it. It could not but be gratifying to them to see almost all the gentry of the country collected together here to view and admire their productions."

Postage.

We dislike to be harping upon this subject; but it is really one of some moment to us. We are in the daily habit of receiving letters by mail, enclosing a dollar or other bill for the Cultivator, with single postage paid, and extra postage charged here to us. This extra postage is generally 12½ or 25 cents, and often 50 cents—a serious drawback upon our profits when taken in the aggregate. We beg our friends to recollect, that every enclosure in a letter subjects us to additional postage; and if it is not paid where the letter is mailed, it must be paid here, where the error is sure to be detected. We are in the annual receipt of four to five thousand letters, which should come to us free of postage, but upon a great many of which we are charged, and charged legally, with additional postage. We beg our correspondents to abate the evil.

Short-Horned Cattle.

The Short-Horns maintain their standing in Kentucky.—At a late sale of Gen. Gerrard's stock, at Paris, Ky. eleven animals of pure improved short-horn blood, sold for $8,157. One, Exception, was bought by B. J. Clay & Co. at $1,830. At the same sale, ten animals of mixed blood, sold for $2,580, averaging over $250 each.

Mr. Whitaker's stock, lately sold at Powelton, near Philadelphia, went off at good prices. The prices and purchasers were as follows:

Dairy Maid, 3 years, $540, J. Gowan, Philadelphia.
Victoria, 3 years, $520, G. Brinton, Pa.
Nunnia, 3 years, $500, C. Warwick, Va.
Viviana, 3 years, $530, W. Heyser, Pa.
Thornville, 3 years, $500, do
Lady Whitworth, 2 years, $530, C. Warwick, Va.
Lobelia, 2 years, $400, W. S. Torr, Pa.
Enchantress, 2 years, $500, R. A. Taylor, Baltimore.
Minerva, 2 years, $360, Dr. Noble, Pa.
Sarah, 2 years, $380, Mr. Beltzhoover, Baltimore.

H. Clay, Jr. lately sold his imported short-horned Durham cow, Princess, to J. & R. Allen, for $2,000! This *is* the climax.

Agricultural Items.

At the meeting of the Highland Society of Scotland, in August, 177 applications for admission as members were made—a pretty good evidence that the society is not on the decline, though more than fifty years old.

Apples may be kept in a dry chamber, over a room in which there is a fire, even in winter. They preserve best in tight barrels; and after they are unheaded for use, they should be kept constantly covered with a linen cloth, in two or three folds. They are not much injured by frost, if they are kept in total darkness until they be used, or become thawed.

An Agricultural and Horticultural State Society has been organized in Michigan, Hon. Joshua Howard, president. They have resolved to petition the legislature to establish a board of agriculture, to make appropriations for the support of a state agricultural paper, and county societies—and to authorize school districts to draw their quotas of the school fund in agricultural works and publications, to such an amount as the finances of the state, and the school fund, will warrant. We are happy to find our young sister thus early engaged in looking to the substantial wants and permanent interests, of her growing family. We hope she will prove a kind as well as a wise mother in these matters, and teach her children to *earn*, that they may know the true luxury of enjoyment.

Grease for wheels and machinery.—M. d'Arcet, the celebrated French chemist, and master of the mint in France, recommends the following composition as the *best grease for wheels and machinery*, viz.: "Eighty parts of grease and twenty parts of plumbago, (black lead,) reduced to very fine powder, and intimately and very completely mixed together. A very little suffices." So says a French journal.

Liniment for the galled backs of Horses.—White lead moistened with milk. When milk is not to be procured, oil may be substituted. "One or two ounces sufficed for a whole party for more than a month."—*W. H. Keating.*

To preserve cheese, we perceive this year, for the first time that it has met our notice, that some of our dairy women envelope the cheese closely in a cotton cloth, when it comes from the press. The process of rubbing the cheese attaches the cloth so closely to the rind, that the cloth is not noticed by a superficial observer. This treatment preserves the cheese from insects, prevents its cracking, and secures to it a thin rind.

Planting of Trees.—Charles Blakeslee, of Newton, Ct. states to us, that last spring he planted out 14 maple trees, in the following manner:—He put them in holes so shallow as to bring the tops of their roots to the surface of the ground. He then brought loam and turf from a hollow, and raised a mound over the roots one foot high, and eight feet in diameter, and covered the mound with small stones. Notwithstanding the drought of the season, every tree thus served lived, while others, planted in the usual way, all died. Mr. B. ascribes his success to the fact, that the small stones prevented the exhalation of moisture, and deterred cattle and swine from rubbing against and loosening them.

Rohan Potatoes.—Last spring, we sent to Mr. Shepherd, P. M. Northampton, Mass. a peck of Rohan potatoes, to be presented to our patrons in that town. We see in the account of the October fair, in that county, what we deem to be some of the products of this seed. W. Clark, Jr. raised from one potato, 2½ bushels; Mr. E. Mitchell, from 4 lbs. of seed, raised 18 bushels, weighing 1,173½ lbs.

A Knitting Machine was exhibited at the Northampton fair, with which a child of 15 years of age can turn off two pair of stockings per day. It costs but $18.

Apple Pomace.—Farmers, save your apple pomace, for your cows or your pigs. If kept from fermentation, it may be fed to milch cows with great advantage. We have known it to double the quantity of their milk. Pigs will thrive upon it after it has fermented. It may also be made into manure, by mixing it in a compost with quicklime and earth—the lime neutralizing the acid and inducing decomposition.

Evergreens.—M. Vilmorin, the great Parisian seedsman, has found that pines, and other resinous evergreens, grow with great luxuriance on land manifestly unfit for tillage or grass—and that they will not grow well upon a calcareous soil. These conclusions seem to be confirmed by the natural growth in our forests—the pine and other evergreens being generally found upon poor sandy lands, and very seldom upon soils abounding in the carbonate of lime.

M. Vilmorin has come to the conclusion, from numerous experiments, that no species of American oaks will succeed in bad calcareous land; and M. Poiteau goes so far as to say, that the soil of Paris has become so eminently calcareous, from the constant additions it has received from old buildings and repairs since it was first erected, that there is scarcely a tree which can grow there satisfactorily except the elm. Those who plant shade trees may profit from these hints.

Silk Culture.—Dr. Perrine has pronounced the morus multicaulis speculation a splendid *humbug*. The doctor insists, that all efforts to raise silk, from the multicaulis, or even white mulberry, north of Southern Virginia, will ultimately prove abortive, both from the coldness of the climate, and the expense of labor. The doctor is certainly in error. Although the public expectation and enthusiasm have been worked up to an unreasonable pitch in this matter, yet we have not a particle of doubt, that where the business is judiciously managed, as a branch of domestic or household labor, the benefit will be palpable, and the profit certain.

Rohan Potatoes.—The price has advanced; and such is the demand for them, that we will not pretend to set to it any conjectural limits. Mr. Thompson, of Catskill, is the only grower we know who has them now for sale. We pronounced their quality *good* for the table. A better opportunity of knowing them, will now warrant us in saying they are VERY *good.*

Potatoes.—1,000 tons of potatoes had been shipped in the Thames, Eng. in October, for the New-York market. The value of the potatoes sent from Maine to southern ports has been stated at $300,000. Five hundred barrels of Irish potatoes arrived at New-Orleans on the 18th November. The price there was $9 per barrel, or fifty cents per dozen.

Texas.—Flour is quoted in this promising land at $22 per barrel; potatoes $7 per bushel, and butter and cheese at 75 cents per pound.

Two bushels of hard Dutton corn, by being boiled a few hours, we learn from the Farmers' Cabinet, have been found to expand to the bulk of five bushels and a peck.

We have received a sample of *tree*—not *tea*—corn, 8 rowed and yellow, raised at Caldwell, Warren co.

The thermometer stood at zero, at 6 on the morning of the 25th November, at our house; at Utica, it was 4°, and at Montreal, 6° below zero.

M. Multicaulis.—A public sale of one year old plants was held in Boston, in November. They were sold in parcels of fifty. The first lots, untrimmed, and five feet high, were bid off at one dollar a tree; subsequently, some lots, partially trimmed, went off at 37½ cents per tree. Cuttings, with two buds to each, were sold at two cents.

The Queens County Silk Company, Md. held their first sale—not of silk, but of multicaulis trees and buds—on the 18th November. The sales amounted to $2,200, and averaged about $50 per thousand cuttings.

To convey grafts of trees, cuttings of vines—and why not seeds?—in safety to a distance, a writer in Loudon's Magazine recommends, that they be placed in a tin case or cylinder, filled with honey. The honey hermetically excludes the air.

New Agricultural Journals.—The *Farmers' Advocate*, a semi-monthly sheet in octavo, published at Jamestown, N. C. by John Sherwood, price $1.25—and the *Michigan Agriculturist*, a weekly quarto of 8 pages, price $2 per annum. The more agricultural journals, the more agricultural readers, and the more agricultural improvement.

The Silk Worm.—According to the Silk Culturist, Judge Spencer, the past season, raised 40,000 silk worms, and lost but 4.

Glass head dresses.—Our foreign journals announce that a new discovery has been made in the manufactory of glass, by which it is rendered so pliable as to make cloth, or fabric, of the finest texture. Pieces have been produced 2½ yards long, and from nine inches to thirty-six inches in breadth; and some very fine ladies' head dresses have been made from this material, which all considered both very curious and very useful.

A new breed of hogs, is noticed in the Michigan Agriculturist, as abounding on the banks of the Detroit river, which will leap "a five feet fence without difficulty." They may be called leapers if not lepers.

The Rhode-Island Society for the Encouragement of Domestic Industry, have just appropriated $150 of their funds, as a subscription to the New-England Farmer, to be awarded in premiums. Bating any interest we may be presumed to have in the precedent, we may be permitted to say, that it is rewarding those who *do well* with the best means of *doing better*.

Premium Butter and Cheese—The Massachusetts Agricultural Society awarded, in December, the following premiums for the best butter and cheese exhibited for their inspection.

$100 to L. Chamberland, of Westborough Mass. for best butter.
$50 to L. B. Hopgood, Shrewsbury, Mass. 2d. best.
$30 to W. Barhop, Barnet, Vt. 3d. best.
$50 to D. Lee, Barre, Mass. for the best old cheese.
$30 to T. Fisher, Burke, Vt. for the best new cheese.

The premium butter sold from 33 to 47 cents per pound. It was mostly exhibited in stone pots.

Berkshire pigs are getting into as high repute among swine, as the improved short horns have become among neat cattle. We had heard, in several cases, of individual pigs being sold at fifty to eighty dollars. The Franklin Farmer, of the 8th December, informs us of the sale of a pair of Berkshire hogs, at the extravagant price of $500! The purchaser was William P. Curd, Esq. and the seller John R. Bryant, of the society of Shakers, all of Kentucky.

Sidney Spring, of Pratt's Hollow, Madison county, N. Y. says he obtained from one-fourth of an acre, one hundred and seventy bushels of carrots, and from the same quantity of land two hundred bushels of mangold wurtzel.

He harvested from five and an half acres, three hundred and twenty bushels of sound corn; two hundred and ninety bushels of which he sold at one dollar per bushel—the nett gains of which, he says, was about $40 per acre. This land he purchased seven years ago, for eleven and an half dollars per acre.

It is stated in the Franklin Farmer, that a cow belonging to Dr. Samuel D. Martin, gave the day her calf was ten days old, 41 quarts of milk.

A cow, the property of Mr. Kent, of West Springfield, has given, during sixty days, beginning in June last, 1346 quarts of milk!! averaging 22½ quarts per day. Largest yield, 11 quarts in the morning and 16 quarts at night.

Cows kept warm and dry in a stable in cold weather, will yield one third more milk than if exposed to all kinds of weather; and while the weather is wet, they will give twice as much, if stabled, as they will if exposed to cold storms.

A pair of Berkshire hogs, from the stock of C. N. Bement, Three Hills Farm, Albany, was lately sold in Kentucky for $250.

The free use of charcoal for hogs, confined in pens, is highly recommended by many individuals, whose habits of attention, observation and experience entitle them to credit.

Mr. Samuel Woodruff, of Windsor, Conn. obtained from twenty Rohan Potatoes twenty and a half bushels, some of which weighed 2 lbs. 13 oz. each.

Mr. Samuel Crary, of Bethlehem, Albany county, killed on the 5th of December last six pigs, between eight and nine months old, which weighed after being dressed, as follows—272, 269, 253, 252, 240, 220—amounting to 1506 lbs. averaging 251 lbs. each.—They run during the summer in a clover pasture, and fed the wash of a small dairy—fattened in the usual way, and no particular care taken with them, as there was no particular object in view, except fitting them for market. Nine dollars per cwt. was readily obtained for them. They were five-eighths Berkshire and three-eighths China breed.

At the Fair of the American Institute, in October last, a silver medal was awarded to C. N. Bement, for his Vegetable Cutter and a small mill for crushing grain for feeding stock. He also received a silver medal for fine specimens of Rohan potatoes, and a diploma for his Turnip Drill, (a silver medal having been awarded him the year previous.)

Notices to Correspondents.

Oaks.—Friend Bull's letter and eight acorns came to us through the mail, charged $1.12½ postage. The acorns must of course go to Washington. It is not easy to determine the species to which an acorn belongs, without seeing the cup and the leaf. From the description of the cup being fringed, we think it is the over-cup white oak, the Quercus lyrata of Michaux.

Indurated Clays.—We have received several samples of earth from Rufus Clark, of New-Brunswick, which have been examined by a scientific gentleman, who considers them indurated clays, similar to those found in various parts of New-Jersey; the white is of a fair quality, and would probably be of service in the manufacture of pottery, and possibly of porcelain.

A gentleman at Maysville, Ky. asks, if the soil he has described to us—a rich loam, which has lain some years in pasture, and has just been ploughed—is suitable for the Rohan potato, and whether we would advise to plant these potatoes and his corn in *hills*, instead of *drills?* We respond affirmatively to all these questions—believing that the culture in hills will be less expensive, and the product equally abundant, as if planted in drills.

Morus Multicaulis.—In answer to the inquiries of S. Rosa, Painesville, Ohio, we are almost disposed to say, that people, now-a-days, esteem that kind of mulberry best, for the manufacture of silk, which they want to sell. We verily believe there is no great difference in the quality of the different mulberries for silk, under household management. The seed of the genuine multicaulis cannot be had. The price of the trees ranges from 25 cents to 25 dollars. The Messrs. Prince of Flushing, *advertise* 65,000 trees, and trees are for sale at Philadelphia, New-Jersey, &c.

Tree Corn.—We have several applications for Mr. Thorburn's Tree Corn, which, we are sorry to say, we cannot supply. It is to be had of the Messrs. Thorburn, in New-York and Albany, seedsmen.

One of our subscribers in Indiana, Joshua Cottingham, writes as follows:—"Since I began to read the Cultivator, I have been adopting some of its recommendations, particularly in regard to rotation of crops. I find that by mowing my clover and grass one season, pasturing it the next, and then turning it in deep for wheat, sowing on the first furrow, and harrowing in the seed well, I get double the crop of wheat that my neighbors do." Now, if Mr. C. raises 10 acres, and adds 10 bushels to the product of each acre, as we may infer, by alternating grain and grass, his gain in a single year, by taking the Cultivator, in his wheat crop alone, is more than enough to pay for the Cultivator as long as he lives, though he should reach the next century. The average product in his vicinity, our correspondent advises us, is 30 to 60 bushels of corn, and 10 to 30 bushels of wheat to the acre; and he expresses a belief, from his own improvements, that the product may be doubled by manuring—a thing not there thought of—and judicious management. There is great danger, that the "skinning" business will be carried to a prejudicial length in the new, as it certainly has been in the old states.

Brussa Mulberry.—Sheldon Basset, of Hector, has sent us sundry interrogatories in regard to this tree.—All the reply we can make is, that the seed was originally brought from Turkey, by Mr. Rhind, we think five or six years ago, and planted by the late D. Ruggles, Esq. at Newburgh. We saw the plants in the springs of 1837 and 1838, on the place of their growth. They appeared not to have been injured a particle by the winter, although much crowded and much of the wood slender. The seed has sold at $10 per quarter of a pound, which quantity has given fifteen to twenty thousand plants. We do not know that there is any seed for sale in this country. The plants may be had at the Albany Nursery, at fifty cents to one dollar each, according to size. The tree, it is presumed, may be propagated like the other varieties of the mulberry. The leaves are six inches or more broad. The growth from the seed last season, in a crowded situation in the nursery, was about two feet.

Acknowledgements.

We have received two apples from Mr. Rotch, of Butternuts, believed to be *vandeveers*, tender, juicy, and of pleasant, though not of very high flavor—a fair, handsome dessert apple, above the medium size and quality. The Tiffin, Ball and Water-fallow, from Mr. Thompson, of Catskill, together with a pear, name unknown, but of flavor strongly resembling the Seckle, in eating in December and January. We received grafts of the Ball and Tiffin, from Mr. Saul, Lancashire, Eng. and sent them to Mr. Thompson, who propagated them. The Ball apple is of mammoth size, flat, the stem inserted in a deep cavity, yellowish green colour, with a red cheek, in eating in November, juicy, but of medium flavor. The Tiffin is a beautiful red apple, somewhat larger than the Spitzenburgh, but of similar shape; flesh crisp, yellow and sprightly—we think an excellent dessert winter fruit. The Water-fallow resembles in size and flavor the Fall Pippin, though later, as it comes in eating after the former is done. It is from the middle states, and may be pronounced as good as the Fall Pippin, with the advantage of keeping longer. Two apples from Vermont, from Dr. James, of more than medium quality—both seedlings. *See seed grain.*

Female Patronage.—Among 29 subscribers received in a letter last week, from the "Bay State," we recognize among them with great satisfaction, the names of *sixteen* ladies.

CORRESPONDENCE.

Great Ruta Baga Crop—Mixing Soils.

Schaghticoke, Dec. 1, 1838.

Mr. Buel—Sir—I send you a statement of the produce and culture of a patch of ruta bagas, which I have raised the present season, the profit of which, if not the greatest, I flatter myself, is not the least, which will be offered for your premiums; as the summer has not been favorable to the produce of large crops of turnips. The soil is a sandy loam, (generally so called,) but contains by far too great a proportion of sand to be termed good, and I think myself amply compensated for applying from 50 to 100 loads of clay per acre, in the increased products of the first two years. The manure was spread and ploughed in immediately before depositing the seed. They were sown the first day of June, in drills about two feet apart one way, and owing to a partial failure of the seed which was old, a foot or 18 inches the other, which I am persuaded was an advantage to the crop, as they grew very large; one weighed over 24 lbs. after being trimmed. The after culture was one dressing of plaster, which I think is of very great advantage to them, especially in a drought; three hoeings or weedings, in which care was taken not to earth them up at all. The harvesting is very much facilitated by using a hoe ground sharp to cut the tops as they stand in the ground, after which they are pulled with a hook; in this way two men will gather seven or eight hundred bushels of them in a day. I had 970 bushels, calculating 70 lbs. per bushel, from 126 rods, at the rate of 1,231 bushels per acre. I had another piece I think equally as good, which were not measured.

The profit of the 126 rods is as follows:

Dr.	To 20 loads manure, at 25 cts.......	$5 00
	Carting and spreading the same, ...	3 00
	Ploughing, rolling and harrowing,....	2 00
	Seed, ...	0 37½
	Sowing, ½ day, ...	0 25
	3 hoeings, 10 days, 6s.............	7 50
	Harvesting, 6 days, 5s.............	3 75
	Interest on land at $100 per acre,...	5 50
		$27 37½
Cr.	By 970 bushels ruta bagas, at 1s. 3d..	$151 56
	Tops for fodder,....................	5 00
	⅔ds manure for succeeding crops, ...	5 32
		$161 88
	Deduct charges,............	27 37½
	Balance, ...	$134 50

Profit $134.50, or $170.80 per acre.

I am trying an experiment in feeding them, which if important, shall be communicated to you and the public.

Yours, &c.
JOHN C. MATHER.

Corn Crop.

Volney, Oswego co. Nov. 27, 1838.

Mr. Buel—Sir—I saw in your March number of the Cultivator, a premium offered on several articles of agriculture; I therefore send you a statement of one acre of corn raised by me this season, hoping that if I do not prove a successful competitor, the cause of agriculture may receive an additional witness in its behalf. The soil is a warm gravel; the corn was the twelve rowed yellow variety. About the 1st of May, I carried on and spread, all over the ground, seventeen loads of stable and barn-yard unfermented manure, ploughed before the manure dried; bushed and harrowed the ground well, being careful not to disturb the sod, which had lain to pasture four years; and on the 14th and 15th of May, planted the same, three feet and three inches apart each way. It was dressed with seven bushels of good unleached house ashes, mixed with one and a half bushels of plaster, when it made its appearance above ground. On the 10th June, went through between the rows both ways with cultivator; 18th June, cultivator both ways, then thinned to four stalks in each hill, and hoed out the weeds. On the 3d July, cultivator both ways, and commenced hoeing; put no more earth about the hills than we took from them, but carefully cleaned out all the weeds from the hills. The seed was prepared by rolling in tar water and plaster. The corn was cut up the 1st of September, at the ground, and shocked in small shocks, and on the 25th it was husked and housed.

The product is 110 bushels of first rate corn, and 6 bushels of second rate, making in all 116 bushels of corn, and four loads of stalks per acre.

WILLIAM INGALL.

I hereby certify that I am personally acquainted with the above named William Ingall, and believe him to be a person of veracity, and that the truth of his statement may be depended on.

AARON G. FISH, *Justice.*

Corn Crop.

Port-Byron, Nov. 8, 1838.

Judge Buel—Sir—As I have been a constant reader of your valuable paper, the Cultivator, from its commencement, and think I have received much instruction and profit by it. I take the liberty to state to you some facts, that I think may be for the encouragement of some farmers.

Some time in March last, I commenced drawing manure from the barn-yard with two boys and a pair of steers, for the purpose of making them handy; the most of the time we used a horse before them. One of the boys lives with me, the other I hired at $5 per month. We drew the manure on a clover ley of three years' standing, about three acres. We put on the whole, 150 common wagon loads, spread it as even as we could, then ploughed, turned it over smooth, rolled and dragged it well, and planted the 11th and 12th of May, with Robbins' drill-barrow; planted what we call the 12 rowed yellow corn, but some ears have 20 rows, and from 10 to 15 inches long. Aimed to have the rows 3½ ft. apart, hills from 1½ to 2 ft.; from 2 to 3 kernels in a hill; rows north and south. I soaked the seed first planted in warm water, with a little salt-petre in it. The drill did not work well; I then took the dry seed and planted the remainder of it, which generally came up well; but before I knew it, the crows and worms had devoured a great deal of it. I planted it over, and part of it the third time, with the little golden corn. It nearly all stood finely. I went through it three times with a horse and cultivator; hoed it well the first time, was not quite so particular the next. I think it the best piece of corn that I ever saw in the state. Sometime the fore part of September, we cut it up at the roots, and stooked it up, but did not husk any until 15th October. It turned out so well, and was so sound, that I thought I would measure an acre, and see how much was on it. So we took the August No. of the Cultivator, the square and a rope measuring two roods long, went to the field and measured an acre, according to the rule laid down in said number; we measured the wagon box, or first load, 24 baskets full, holding almost 1½ bushels each; we had on the acre 169 baskets, or seven loads and one basket. We took one basket out of the heap, just as it came, and shelled it, and it weighed 37½ lbs. We husked a load more, and Mr. Cronkhite, one of my hands, thought the corn was still better; we then measured another acre as accurate as possible in the same way, 12 rood 3 feet by 13 rood 2½ feet; we husked off of that 166 baskets, or seven loads, wanting two baskets; we shelled one basket as before, and it weighed 39½ lbs. of shelled corn; the corn was husked and thrown down, the wagon going round to gather; shook down the corn, so that the loads might have been a little larger, and the corn rather sounder, as there was not so much damage done on the second acre by crows, &c. Thus you see, the first acre had on it 112 bushels 23¼ lbs. of shelled corn; the second had on 118 bushels 28 lbs. or 118½ bushels; the second acre had on it eight loads of pumpkins; the stalks are well saved, and are excellent fodder. I sowed turnip seed on the whole piece, but the corn and pumpkin vines so covered the ground, that the turnips are worth but little; a few bushels grew to good size since the corn was cut.

EXPENSE OF CROP.

I am yours, with great respect,
JOSEPH F. OSBURN.

Mentz, Nov. 13th, 1838.

This may certify, that I helped raise the said corn, or tend it, and measure, husk, shell and weigh it, and believe the above to be true to the best of my knowledge.
JOHN HADDEN.

This may certify, that I helped measure the 2d acre as above, and husk it, and believe the above statement to be true. ABRAM KELLS.

P. O. Port-Byron, town of Mentz,
Cayuga county, 17th Nov. 1838.

I am personally acquainted with Mr. Joseph F. Osburn, and have no hesitation in saying that his statement contained within, is in all respects true; and further, that any statement in agriculture coming from him may be relied on. HORACE PERKINS, P. M. & J. P.

Legislation and Agricultural Education.

Clinton College, Tenn. Nov. 13, 1838.

Hon. J. Buel—Dear Sir—No subject interests me as much as the improvement of the soil and the mind, taken together, as the great business of our nation. And your remarks under the head of "the crops," in No. 8 of the Cultivator for the present year, are so full of the spirit that should actuate all Americans, that I must beg leave to quote them, and I wish they were published again and again, in large capitals. "*Will the politician, the manufacturer, the merchant, and the mechanic pause a moment and reflect upon the controlling influence which the abundance or scantiness of the harvest has upon the prosperity of our common country, and upon their several pursuits? If the harvest is abundant the whole land is prosperous and happy. If the harvest fails, every class feels the electric shock, business becomes stagnant, embarrassments multiply, and the whole land mourns. How important is it then, that all should feel and exert a direct influence in encouraging and qualifying the husbandman to increase the products of the soil—by legislative patronage, and by a system of enlightened education, calculated at once to make better farmers and better citizens.*" I have quoted your remarks all in emphatic characters, because they contain an idea that should be brought home to the full investigation of every American.

Of all the citizens of the U. States, perhaps, eighteen-twentieths are farmers, and if these do not prosper, the other classes cannot. The merchant cannot sell his goods, nor the manufacturer, nor the mechanic his labor, because the farmers who are their customers are unable to buy. The physician cannot prosper, because eighteen-twentieths of his patients are farmers, and unable to pay him liberal fees. The lawyer can not prosper, because eighteen-twentieths of his clients are farmers. The minister of the gospel cannot prosper, because eighteen-twentieths of his hearers and congregation are farmers. The politician cannot make his nation prosperous, because eighteen-twentieths of those who support the treasury are indigent farmers, and money is necessary to carry into effect the measures of the nation. From all this, which must be evident to every one, it appears to me, that our politicians, both of the Union and of the states, have always been legislating at the wrong end of affairs. Roads, banks, schools and commercial facilities, seem to have engrossed their whole care. It is true that these are all desirable blessings, but they are the *result* of wealth, much more than the *cause* of it. Roads and colleges cannot be made without wealth, and banks are useless when they have no money to represent their paper. If the states would adopt a course of legislation that would bring all the talents in them to bear upon their soils, wealth would soon be so abundant that roads, and colleges, and banks would be made wherever they are needed. Fluctuations in the money market would be less frequent and less distressing; for the money in the country would only keep pace with the wealth in it, and there would be less fictitious bank notes created by legislative authority without money to redeem them. But instead of all these blessings, we have none of them to a great extent. Thus it is that one radical error in the community produces a thousand errors and difficulties. Nature made our country principally for agriculture, and the neglect of it, throws every thing else into confusion and distress. Heaven has made no two countries precisely alike and for the same purposes. Then if the inhabitants of any country direct it to the end for which it was created, that nation will be prosperous; but if any country be directed to a different purpose from the one for which it was created, then disppointment and poverty must be the consequence of such perversion of Heaven's laws. It is vain to legislate for the objects which complete a nation's happiness, when the whole country is crippled in its operations by being diverted from the very end for which it was created. Let us have a universal system of scientific agriculture, practised every where in our country, and the observance of the laws of nature (Heaven) in that one branch of business, will soon give us a sound currency, good roads and good schools, as well as all other blessings we desire. Had nature made our country exclusively for manufacturing or for commerce, then there would be great good sense in directing the efforts of our government and our people to commerce or manufactures. In such a case it would be superb folly to make agriculture our absorbing care, to the neglect of the very purpose for which our country was created. But suppose our country were *mainly* created for agriculture, and provided with fertile soil, congenial climate and facilities for exporting our products to every part of the world, what would you think of our government, if it were to direct its efforts to the fostering of commerce and manufactures exclusively, while agriculture was neglected? Would you not say, that as a nation we have reached the summit of foolishness? But precisely such, (shall I say it? O! shame for boasted U. States!) the truth must be told, precisely such is a true but imperfect picture of our country, and of the movements of our government. Has Heaven made such a variety of salubrious climate, and such an immensity of the richest soil in the world, to be thus neglected, or thus frolicked away? How long will our people suffer themselves to be intoxicated by the political buzz and party spirit, which our politicians perpetually keep up, while they overlook—proudly forget—and even spurn to condescend to the true, the vital interest of the country. It is high time for us to rise and assert our rights. Let us vote down at the ballot box every puffed politician who would lead us away from our main interest, by filling our heads exculsively with Van Burenism, Clayism, Websterism, Whiteism, Harrisonism, Jacksonism, or any other mere partyism. Let us make them speak out and act out for the interest of our country or leave them at home, and select other lawgivers who *will* study this vital blood of our nation. It is vain to disguise any longer; to this point we must come at last. Our soil is every day washing from under us, and he is no patriot, no friend to the people, who would make them forgetful and drunk enough, on a mere ism, to frolick away their homes. It is high time, too, that the newspapers, which so pervert and poison the community, shall be commanded to stop their mad—their whirlwind—their baneful—their ruinous career. No man can study the sober interest of his country or his farm, if he reads them, while they are thus full of every thing that is slanderous, intoxicating and poisonous. Newspapers are very useful, so long as they are conducted with sober truth, and patient good sense; but when they are ever ready to sacrifice truth, philosophy and the vital interest of the country for mere party purposes, they are vile scourges to any nation. Let us then induce them to a season of sobering and reflection, till they become decent things. Let those who spend $20 a year for newspapers to heat their blood, curtail their reading of this kind, and spend $5 for agricultural papers that will make them prosperous, and their children—and their country, happy. But few men can in truth affirm that they have warrantee deeds to their farms while they confine their reading exclusively to party newspapers; because their soil will depreciate and wash away to the gulfs and oceans, and thus leave their deeds located upon sterile clay or sand. Then let us unite upon those measures which will save and improve our country, by bringing the individual and national mind to bear upon and develop all the natural advantages of the soil. The literature of our country needs remodeling. Though I am not old, I have spent most of my life, thus far, in teaching science, with a farm under my care. And I am ashamed, that so little of our boasted learning is practical—tamed—domesticated, and familiarized to the avocations of men. When the young man graduates with honor, he is then unfit for any occupation—he has still to learn his profession. Whereas, the college or university ought to fit young men at once for the occupations they are to follow. To promote these ends in agriculture, I propose to add $20 to the premiums offered by Mr. Solon Robinson and yourself for the publication of certain agricultural books, as described in the 8th number of the Cultivator. I also unite with Mr. Robinson in petitioning for an American Agricultural Society: and I join with him heartily in the proposed national petition to congress for the establishment of a National Agricultural School. And I would suggest that the Smithson bequest, lately received by the U. States, of £100,000, is the fund which should be set apart for that purpose, provided there is nothing in the *will* of the liberal Mr. Smithson to forbid it. Your ob't servant.

F. H. GORDON.

P. S. A convention of delegates from the societies of agriculture in our state takes place at Lebanon on Monday next.

Hoeing Wheat.

Hector, Tompkins co. N. Y. Nov. 27, 1838.

J. Buel—Dear Sir—I have seen an article in your paper, headed "*Wheat on Clover Ley.*" I have been in the habit of growing wheat on clover ley, for nine or ten years past, and find great benefit resulting from it. The only difficulty that I find resulting from this mode of farming is, that on moist ground, after an unfavorable season for preparing my ground, grass has grown with my wheat in such quantities as to destroy say from two to four or five bushels of wheat to the acre. In 1837, I attempted to plough in about three acres of clover; at the time of ploughing, the season was dry, and the ground so hard, that when I finished ploughing it, I considered that about one-third of the ground was left unbroken by the plough; this ground was a part of the same field where I had corn then growing; I could not improve it any as a pasture; I ploughed this ground again after the middle of August; the season had continued dry, and the clover had not rotted, and my plough drew up the clover into heaps, like ploughing in straw, and when I had finished ploughing this time, much of the ground remained yet unbroken by the plough. I sowed this ground with wheat, I believe the 9th day of September; it was so badly prepared, that I think I should not have been disappointed if some part of it had not brought five bushels of wheat to the acre. Early the next spring, this wheat appeared to promise a good crop, but I soon found plenty of grass growing with it. I soon visited this wheat again and took along my hoe, and began to hoe up some of the grass sods, placing some on stones, and others in the place where I had taken them from, with the roots of the grass upward. I soon found that I did not disturb the wheat much, the roots of the wheat not being interwoven with the grass roots. I continued hoeing this wheat at intervals untill I had hoed it twice over, and some part of it three times. After this wheat was fully grown, one of our best farmers, knowing that this ground was badly prepared, examined this wheat, and found it so clean from grass and so good a growth, that he gave it as his opinion, that if it should fill well, it would bring me twenty-five bushels to the acre, or nearly that. This wheat, like most of the wheat the past season, was not well filled, and was not kept separate from my other wheat, having no intention at the time of tilling of communicating this beyond my immediate neighborhood; I kept no accurate account of the time spent in hoeing this wheat, but concluded at the time, that it amounted to about one day, or a little more, on each acre; and at the time of harvesting, concluded that this ground had brought me, in return for hoeing it, about eight bushels of wheat to the acre. Although I cannot ascertain the exact benefit resulting from hoeing this wheat, yet I feel confident that where my wheat has grass growing with it, it will pay me as good wages for hoeing it as my corn will.

I ought to have said that twenty-five bushels to the acre would have been as good a crop as I ever had on the same ground. SHELDON BASSETT.

Recipe for Curing Hams, Pork, &c.

Schenectady, 8th December, 1838.

Sir—In the November number of your Cultivator, is a recipe for salting pork and hams. If you are of opinion that the following mode is better, and that the public may profit from a knowledge of it, you may give it a place in the Cultivator.

I rub fine salt, with molasses and salt petre on hams, and pack them as close as I can in a cask. After a day or two, add pickle. In a cellar where it does not freeze, thirty days is long enough for hams not over 20 lbs. to lay in pickle. I use iron hooks, made of wire 1-4th of an inch thick, one end sharpened and turned short to hook into the ham; the other end turned wide, to hook over a pole of two or three inches diameter, and the hooks are six or seven inches long after they are made.

I hang up the hams a few days to dry, and then smoke them. Immediately after smoking, I hang them in the larder or store room, and slip over each ham a bag made for the purpose, of stout and close cotton or linen, and with a string tie it as tight as possible round the hook, and *above the ham*, so that a fly cannot enter or deposite her eggs on the ham, and the hams remain perfectly free from worms through the summer, or any length of time, as fine as when bagged. The hooks are cheaper than strings, as they last an age, and the bags, if kept for this purpose, will serve for many years, if kept perfectly free from holes, &c.

If hams are not bagged till March or April, the flies may have deposited eggs on them, and they should be examined weekly to learn whether insects are on them, to be removed.

I object to the advice of packing hocks and jowls, with the hams, to save pickle, as it will not allow room for enough pickle to save the hams. Many years ago, I packed pieces of pork among the hams, to make it compact, and after the hams were smoked, found they had not taken sufficient salt, and were tainted so early as the month of March.

If hams are packed closely, in a cask of much size, there will not be too much room for pickle enough to save them.

I use pickle saturated with salt in all cases. When it is not convenient to use casks, hams will cure equally well, by mixing so much molasses (or sugar) with fine salt, and ruhbing them together till like pretty dry sugar. Lay the hams, skin down, on a wide board, one end drooping. Rub on the flesh parts, the salt and salt petre thus prepared. After a day or two, the molasses will cause the salt to dissolve and run off; set a vessel under the lower end of the board to receive the pickle, which you can baste on the hams, after adding more salt to the hams, as it melts and runs off. Thirty days is long enough, when pickled as above. I have used an ounce of salt petre, and a half ounce to each ham of 16 or 20 lbs. and found no difference in the hams when used.

The observations of friend Comfort. in preparing and smoking his hams, are very judicious.

I think pork better without salt petre; it may be packed, skin down, each layer, covered with coarse salt, which is preferable to fine salt, except for rubbing on each piece of the pork before packing. After the cask is full, cold water filled to cover the pork, provided salt is put on, so as not to diminish that used in packing the pork: or pickle may be boiled, with some sugar or molasses, if sweet is preferred. Put some pearlash or salæratus in while boiling, as it causes the scum to rise, and clear the pickle, and the scum must be skimmed off.

If mice are in the room, they can crawl up the wall, over the ceiling, and descend to the ham. To prevent them from lodging on the ham, take a smooth and stiff paper, make a hole in the centre of the size of the wire, and slip it on the hook from which the ham is suspended, to form a cap above the bag. When the mouse passes down on the hook to the ham, he will slide off the paper to the floor. and must commence a new journey on the wall. Most respectfully,

DAVID TOMLINSON.

Spring Wheat and Ruta Buga in the Southwest.

Steubenville, (Ohio,) Dec. 5, 1838.

Mr. Buel—While I am writing, I will state to you one or two facts, which may be of some interest to you. The first is, that the ruta baga crop so far as I can learn, failed entirely in this neighborhood, the last season. The second is, that the Italian spring wheat with me was a very poor crop. I sowed something over two bushels of seed, fine looking grain, obtained from Mr. Hathaway, of Rome. It was sown in a field a part of which was in winter wheat. The spring wheat was sown on a rich sandy soil, (Ohio River Bottom,)—straw good—ears formed good size, but much blasted, and much of the grain shrivelled; whole crop 19½ bushels. The winter wheat adjoining 27½ bushels to the acre.

I am afraid that ruta baga and spring wheat will be an uncertain crop here on account of the warmth and dryness of our summers and falls. The last summer was very warm, and the latter part dry. Some seasons, I have no doubt, they will succeed well.

I intend to try beets, as a substitute for turnips.—Beets are as sure a crop as we have. Has the comparative value of a good crop of beets and turnips, in our country, ever been ascertained? If beets will afford as much nutriment as turnips, allowing both to be a good crop, I suspect very much we must adopt beets here. Yours very respectfully,

J. H. HALLOCK.

Experiments in Planting Potatoes.

J. Buel, Esq.—I procured of J. A. Thompson of Catskill, in May last, 9 Rohan potatoes, weighing one pound, gave a friend one of about the average size, planted the eight potatoes, two sets in a hill; the 8 potatoes planted 75 hills, producing 199½ lbs. being at the rate of 221 bushels to the acre: I will here mention that I have allowed 60 lbs. to the bushel, and 5,000 hills to the acre; the hills a little less than 3 feet asunder, each way.

I planted the same number of hills with the common white potato, 2 sets in a hill, which produced 186½ lbs. being at the rate of 207 bushels to the acre, making a difference of 14 bushels to the acre, in round numbers, omitting fractions.

I will here remark, that it took 15 of the common potatoes to plant as many hills as the 8 Rohans planted; making a difference of nearly half in the quantity of seed.

Planted 20 hills of the common potato, with one potato in a hill, which produced 56½ lbs. being at the rate of 235 bushels to the acre.

Planted 20 hills of the common potato, half a potato in each hill, which produced 50½ lbs. being 210 bushels to the acre.

Planted 20 hills of common potatoes, with two sets in a hill, which produced 48 lbs. being 200 bushels to the acre.

Planted 41 hills pink-eyes, with two potatoes in a hill, which produced 99½ lbs. being 202 bushels to the acre.

Planted 41 hills of pink-eyes, with one potato in a hill which produced 66¾ lbs. being 135 bushels to the acre.

Each variety of the above potatoes were as near of a size as I could judge; were all planted on the 26th of May, and all received the same treatment. The tops of the Rohans were green when the frost killed them, about the middle of October, and I am inclined to believe the potatoes had not got their growth, for I should think that there was not any that would weigh over one pound, although the land was in a high state of cultivation.

Should the above experiments with different varieties of potatoes, and different quantities of seed, induce any one of your many subscribers to try experiments, and ascertain the proper quantity of seed, I should consider myself abundantly paid for my trouble. SHERMAN BASSETT.

North-East, Dutchess Co. Nov. 15, 1838.

P. S. The tops of the common potato, with only two sets in a hill, sent out laterals, and shewed to all appearance nearly as many tops as the hills planted with the whole and half potato. S. B.

How to Eat your Potato and to Plant it.

New-Haven, Vt. Nov. 12th, 1838.

Mr. Buel—Sir—As the potato crop the present season has proved, generally, to be very light, perhaps it may be of use, to some at least, both to plant the potato and to eat it. I will just give you a sketch of an experiment I tried on raising potatoes from what we call the seed ends. While fattening my hogs last fall, (whch was done principally on boiled potatoes,) I cut off the seed ends, or I took off from one-fourth to one-third of the potato, according to the shape of it—if long one-fourth is sufficient, if round more is necessary, that the piece taken off may be thick enough to retain moisture sufficient to preserve the chit through the winter. I continued cutting off the seed ends until I got twenty bushels of them, boiling the remainder of the potato for the hogs. When cold weather came on, I buried them on sandy soil, and let them remain until about planting time. I then took them out, planted in hills, each three feet apart, put one piece in a hill, generally, if very small, two. To satisfy myself that they were as good as the whole potato, I planted four rows of the whole potato, of good size, by the side of the seed ends. When I dug them, I found those from the seed ends to equal the other in measure, and to beat them in size. J. L. ELDREDGE.

The method of planting the eyes, and eating the potato, has long been practised in some parts of Europe. In this case the eyes are taken out with a scoop, somewhat resembling a salt spoon, though larger.—*Cond.*

Proper use of Clover Leys—Advantages of Agricultural Periodicals.

Gt. Barrington, Mass. Dec. 12, 1838.

Mr. Editor—I often hear the remark from intelligent men, that such and such soils are not very strong; that they require a great deal of nursing, otherwise are soon exhausted. For my own part I claim but little knowledge of the properties of soils for retaining fertility; but it does seem as though some labored under a very great misapprehension in this matter. Undoubtedly there are some soils so porous—so much exposed to the operations of heat and frost, wind and rain, that they are sooner exhausted of their fertility than those that are more compact and more adhesive. Still let there be a fair representation of facts, and I imagine there is not the difference in the properties of soils, in the same neighborhoods, that some suppose. For instance, in the valley of the Housatonic there are many farms that extend from the river to the adjacent hills, embracing three varieties of soil—the alluvial, which is sandy; the table land, which is a gravel; and the upland, or hilly, which, perhaps, may likewise be termed gravel, but of a different texture from the former, and is stony, and very rough and uneven. The first are natural meadows, and, when annually inundated, very productive of grass and requiring no manure. These are often permitted to remain undisturbed by the plough for years in succession, and, notwithstanding, yield a great burthen of hay: still, according to Professor Hitchcock's analysis, they contain but a very small proportion of *geine*, or vegetable food, less than most other soils in the county; the annual inundations restoring the fertility exhausted by continual cropping. The second variety, the table land, or gravelly, are light, dry, and requiring but little labor and strength of team to cultivate; and, in consequence, are exhausted by a succession of crops, without any regard to judicious rotation. But the rough, stony uplands and hills are more difficult to plough, and are allowed to remain in grass or pasture much longer, and thus recover their exhausted strength—hence they acquire the character of stronger soils. There are lands, in this vicinity, of the same character as those which require so much "nursing," which are, every year, improving in fertility and value, and it is a remarkable fact that these lands which are thus improving, were, a few years since, considered as very inferior and hardly worth the cost of cultivation. The proprietors of these lands, in some instances, have hit upon a course, which, if varied in some respects, appears to me the proper one for such lands. Almost uniformly clover, (with plaster,) is used as an ameliorating or enriching crop; yet the *land* is but little benefitted thereby. For as soon as the clover has attained to such a height that cattle can "get a good bite," while the herbage is tender, and before the stalk becomes in the least indurated, the cattle are turned upon it, and continued there as long as they can get a living. Then comes the turn for colts or sheep, which continue the spoliations till the field is a complete waste, and almost as barren of herbage as the Lybian desert. And now, perhaps, it is time to put in the plough for a winter crop; so the soil is turned over, and if ten bushels of rye, or fifteen or twenty bushels of oats per acre are obtained the proprietor is entirely satisfied.

Now, Sir, it strikes me that this is a mistaken policy. It is true that the stock that takes the first clip fares most daintily, and the land is somewhat benefitted by the manure left upon the surface; but, in the case of a dairy farm, where the cows are often driven a considerable distance from the pasture to the yard, there is a great waste; though many never think of that. But the root of the clover thus sheared of its lungs can never attain to much size; and as hardly a leaf or a stalk is turned under, the soil can be but little benefitted by the green crop; and if it does not degenerate it does not improve.

About three years since, in July, I called on a gentleman in the north part of this town, who makes use of clover "according to my notion" of the right way. He went with me over a considerable portion of his farm, and through fields which he intended to sow with wheat or rye. The soil was a gravel, and, by nature, not the most fertile. In these were horses, swine and cows, up to their eyes in clover in full bloom, and of most luxuriant growth: and I assure you it gave me pleasure of no ordinary degree to witness such a feast—a feast for the eye, for the brute and for the soil. I remarked, "Indeed Mr. T. your stock fare sumptuously." "Yes," was his reply, "and that is the way I manure my fields. When the clover is pretty well rolled down—I don't allow the cattle to *eat it all up*—I go in with my harrow and complete the levelling process by drawing it in the same direction that I plough, that in the latter operation the herbage may be more completely buried." He likewise told me that it was by far the cheapest manure he could use, and that as long as he could produce clover in such abundance he would not draw manure if it were *given* him. This is carrying the principle to its fullest extent—further than I should approve: but it might have been his extravagant manner of showing his entire confidence in the system of cultivation, independent of other means of fertility. Still I very much doubt his willingness to *give away* his yard manure, or to part with it for the market price; and I did not observe that he "*summered*" any. He need not have told me that he obtained large crops—they were splendid—for his oats in adjoining fields proved it. By the way, oats are the crop he most cultivates. The land in this region is often ploughed in the fall, and only harrowed (but that *thoroughly*) in the spring.

These lands, thus managed, I have observed are rapidly increasing in value and productiveness. 'Tis strange—surpassing strange—that some people have such short vision that they can not see the simple causes of their neighbors' thrift! There is no necromancy—no *exclusive* knowledge in the process. And here I would allude to the benefits of agricultural periodicals: those who read, observe and practise are the most enterprising, the most successful and the most valued citizens. 'Tis they who bring wealth into a community; 'tis they who make a community prosperous; and 'tis among such that the advantages of society and education are most amply enjoyed. It is by the perusal of agricultural periodicals that I have acquired what little I possess of taste for agriculture, and, in a great measure, my knowledge of the art; though I have but recently commenced connecting practice with theory.

But I have trespassed far more upon your time and patience than I intended. The hope that the hints I have thrown out may be of service somewhere, has been the inducement to offer them for your consideration, and for publication if deemed worthy of notice. Yours respectfully,

F. WHITING.

American Society for the Diffusion of Useful Knowledge.

Concord, N. H. Nov. 24, 1838.

Hon. J. BUEL—Dear Sir—I am one of your constant readers, and am ready to bear testimony to the great value of the Cultivator to farmers. No farmer should be without a copy of it on his table, and he who hesitates on account of the small price, has yet a lesson to learn in the way of economy. Although I have the care of a large farm, I find some time to read—and a part of my time I devote to public service.

My favorite subjects are AGRICULTURE and EDUCATION, and as a father and citizen I am fully persuaded, that the moral character of our people will not only depend upon the elevation of *Common Schools*, but on the nature of the pursuits which are recommended to our children, after they shall have become free and prepared to act for themselves. I have confidence in the integrity of *Farmers*. I believe that the cultivation of the soil is eminently calculated to inspire the higher sentiments of our nature, and to strengthen and increase the devotional spirit. I would say of the farmer what has been said of the astronomer—*an undevout farmer is mad.*

I believe, dear sir, that our institutions, in the hands of farmers, *are safe*. As much cannot be said of any other profession. I do not speak this in disparagement to other vocations—far from it: I mean simply, that it is the duty of all to lead young men out of large towns to the country, to cultivate that soil which is endowed with an amount of wealth not to be counted, and which is capable of sending forth the tens of thousands of beauties which adorn all external nature, and which, in its diversified productions, sustains the whole world.

But I digress—my first object in writing you was, to notice an article in the Cultivator of this month on "*Common School Libraries.*" Your remarks upon the importance of such libraries are just, and show, in my opinion, that you are able to do much good in exercising you influence in their behalf. Two or three months since, I saw a number of the *Charlestown Aurora*—or rather I believe they call it the *Bunker-Hill Aurora*—in which the editor makes an attack on the "*American Society for the Diffusion of Useful Knowledge.*" It was stated, that the members of that society, or most of them, were elected without their knowledge or consent—and that the whole matter was managed by a few individuals—who cared for nothing but for the profits of the concern. I have no objection to seeing my neighbors doing a good profitable business, "not I,"—but I like to see profession and practice agree. Believing that the plan of school libraries was one fraught with incalculable blessings to the rising generation, I took pains to ascertain the acts of the case, so far as my means of communication would allow me. I found that the Bunker Hill paper was right in its conjectures, and to my pain, I found that it did not tell half the story.

The amount of it is, that the society was planned by Mr. Abbott the secretary, and more as a speculation than any thing else. I found that many of the individuals printed as members, were made members without their knowledge or consent—and some of my friends are of the number. I found that the library of fifty volumes, was made up of the *old volumes* of the "Family Library," and the "Girls' and Boys' Library," printed from the old plates, and the only variation was in the binding. These series were published by Messrs. Harpers, of New-York.

Many of the volumes are excellent works in their way, but most of them are not adapted to the capacities of the young. A particular examination must convince you of the truth of this ascertion. Besides, the committee of the society consented to make a statement, which is little less than downright deception. Under the head of

"EXECUTION OF THE PLAN,"

it is stated, "all the arrangements for carrying the design into execution, are in a state of forwardness, so far as they can be, before the necessary funds are secured. It is estimated that $15,000 are required to manufacture the stereotype plates for 50 volumes," &c.

Now, the very volumes offered, are printed from plates that have been used for several years, and on examination of some of the volumes, you will find that they have *two title pages*—one 1835 or 1836 and another 1838—proving that they were printed two or three years ago!!! Much more might be said, but I am no writer, and must beg that you will excuse the matter for yourself. If publishers wish to get off their old stock, let them say so: but in the name of heaven, let not the friends of education come forward with any plans of deception. As yet New-Hampshire has done but little to advance education—but we have made our best plans to be proposed at the next session of our state government. Old Massachusetts is marching forward boldly and grandly in the great cause. I am quite pleased to hear, that the board of education of that state, have decided to have prepared two series of 50 volumes each, adapted to children of different ages, to be edited by some of the most distinguished men of our country. This is as it ought to be—and I can but say to the disinterested and philanthropic gentlemen of that honorable board *God speed.* I am respectfully yours, S. H.

Hints in Rural Economy.

From a Female Correspondent.

Mr. BUEL—I have just been reading in the Cultivator an inquiry as to the cause of pork shrinking and swelling in the pot, and have a few remarks to offer in reply. My father-in-law, old 'Squire S——, you know, had been a great farmer, and not an unobserving one. He accounted for it in this way, saying, that any man of observation, who fed his own hogs when fattening, would see, that during the increase of the moon, hogs ate, at least one-third more, than in the decrease; that they should be killed, when thriving, *just before full moon*; that in the old of the moon, when they eat less, their vessels would be comparitively empty, which caused the shrinkage in the pot. Whether his philosophy is correct, I am not able to say; but the fact is indisputable as to the different stages of the moon.

I will mention one or two more discoveries, made by myself, which *may* be of use, if you think them worth inserting. During warm weather in dog-days, the best house-keepers, who have but a cow or two, and are obliged to let their cream stand two or three days to collect enough to churn, are often troubled with having their milk or cream separate, and a *whey* settle at the bottom of the vessel, which makes the butter a long time in coming. To correct this evil, take a lump of pearlash as large as a walnut, to six or eight quarts of cream, dissolve it in a pint of cold water; by stirring that into the cream before you put it into the churn, it becomes thick, like cream in the fall, and the butter will come very soon, and be as yellow and hard as in autumn.

In raising silk-worms, I experienced a difficulty which I hear nothing said of, but with me was the greatest I met with; indeed the only one; which was, to find something they *liked* to wind their cocoons on. I tried split sticks, dried twigs of every kind, but they would run from them all, until I got some fine *thrifty* sprouts of the Lombardy poplar, which I suspended over them, the ends of the branches just touching their tray. They immediately began to go up, and as the leaves which were long, began to wilt and curl, they formed little envelopes where they soon began to wind, and when taken down there were several branches where *every* leaf contained a fine *large* cocoon. There were several worms which had commenced spinning on the side of the tray, that left them, and took to the leaves, and not a single one attempted to stray, after the poplars were hung up.

Mode of Improving Peat Bogs.

To JUDGE BUEL—Sir—In a recently published account of the proceedings of the eighth meeting of the British Association for the advancement of science, I find the following notice which may be interesting to some of the numerous readers of the Cultivator.

"Dr. Adams communicated some observations on Peat Bogs, the purport of which, we believe, was, that by burning off the surface and sprinkling the subsoil with sulphuric acid, it would become fertile, and that the surface moss, if removed to the farm-yard, and also sprinkled with sulphuric acid, would become excellent manure. In reply to a question by Prof. Buckland, Dr. Adams said, that in some parts of Ireland it was the custom to burn off the spongy part, sprinkle the acid over the ground, and it became prolific. The moss was also prepared in the farm-yard. Major Portlock said he was aware of the practice, but believed it was done, not only for the purpose of converting the peat into manure, but also to correct some deleterious quality in the peat. Prof. Sedgwick suggested that something should be distinctly ascertained, and communicated to the Association at their next meeting, for the subject was one of importance. The principle, no doubt, was, as Major Portlock had stated it, to destroy bad vegetation by means of poison. It must be recollected, however, that the peat moss was of the utmost value to the poor peasantry of Ireland. Mr. Bates said that he had tried a similar experiment thirty years ago, and in the first year the peice of ground was rendered very prolific. But he tried it the next year and did more mischief than he had in the first instance done good."

It is well known that many of the salts, of which sulphuric acid, or oil of vitriol, forms one of the constituents, are highly useful as manures. May not this in some cases, be owing to the acid which they contain? Would not it be worth while to determine, by a series of experiments, the effect of a *very* dilnte oil of vitriol upon soils of different kinds? B.

The Season in Indiana.

Lake C. H. Ind. Nov. 25th, 1838.

It is worthy of note that the drouth still continues in this section of the country to a distressing degree. The old adage, that, "winter never with rigour sets in, till the swamps with water are fill'd in," is completely falsified. The general character of the weather eight months past has been thus:—April cold and dry; May warm, without a single shower; June hot, with two or three days about the 10th, of excessive rains and scalding hot; July and August constant sunshine and south wind that engendered much sickness; September and October continued dry sunshine, with two or three small showers and as many drizzly days, but not rain enough to prevent a complete exhaustion of springs, ponds, streams and marshes, &c.

November, the first days, warm and pleasant, Sunday night the 4th a snow fell about three inches—the 5th, 6th and 7th misty, and snow melted and came off excessive cold, destroying great quantities of potatoes and turnips; then moderately cold until the middle of the month, when the cold increased, and Sunday the 18th was a most severe cold day, freezing the ponds over, strong enough to bear a man. Since then it has been moderate, but now, the 25th, is again very cold. Cattle have required feeding all the month, and in many places water for stock is very difficult to be had.

This has been a season of suffering in the west.

Yours &c. SOLON ROBINSON.

Barilla Ashes—Drill Barrows.

"The ashes from Barilla, are for the most part stronger than any other, and if the same quantity of them were laid upon land as is commonly done with wood ashes, they would burn and destroy the crop. The ashes from the Barilla is a strong rich manure, and sold at 5*s.* per cart load. This excellent manure was first used by the Flemings with great success. Two loads of these ashes are sufficient for an acre of arable land. They should be laid on the ground when the weather is inclined to be wet, in order that the rain may more easily dissolve and wash them in.

"They are generally made into composts with earth and well fermented dung; in the proportion of two loads of dung, to one of earth; the ashes are then added in the quantity of one load to ten of this mixture, turning over, and incorporating the whole completely. Laid upon grass-land in the end of autumn, this manure produces a deep verdure during the winter, and an early vigorous vegetation in the spring; it is therefore particularly calculated for cold wet pastures. One writer remarks that he never uses it alone on account of its hot burning quality; his method is to make a large heap, two parts of earth to one of dung placed in alternate layers to rot. After this has undergone a strong fermentation, he causes the whole heap to be turned and well mixed, leaving it for some time to mellow, then mix one load of ashes to ten loads of compost, leaving the whole to mellow together.—About the latter end of September he causes about ten loads of this compost to be laid in little heaps on each acre of land intended to be sown with wheat; it is immediately ploughed in with the seed. He has also tried this manure on lighter lands, and found it to answer well, provided it has lain a considerable time in the compost heap to mellow, and lessen its natural heat and causticity; but it agrees best by far with clayey soils, and on such is worthy of being recommended as an excellent dressing for wheat crops. As soap makers use much lime to deprive the alkaline salts of their fixed air, the addition of lime to the ashes is unnecessary."—*Complete Farmer, English Edition.*

The reading of this account of Barilla ashes encouraged me to use them to a considerable extent. They have been tried by several of my neighbors on wheat and rye fallow, with good effects on the grain crop, but more particularly so on the succeeding grass.

In all the *drill-barrows* that I have noticed (except my own and those made after them,) the rollers for pressing in the seeds have been *convex*. Mine are made *concave*, about one inch deep in a breadth of three inches. This in my opinion has the effect to press the earth around the seeds as well as upon the top of them. Besides if heavy rains soon fall, after planting, it has seemed to me better for the water to stand and settle a little off, rather than immediately upon the seeds. ROB. WHITE, Jr.

Shewsbury, N. J. December, 1838.

Farming in North Carolina.

Mocksville, Davie county, N. C. Nov. 19th, 1838.

Judge Buel—Dear Sir—Having lately become a subscriber to the Cultivator, (the first in this county I think,) I am much pleased with the character of the work; it certainly contains a great deal of very useful information for the farmer, such as I felt the want of myself, and I know it is the same case with my neighbors, as I don't know of a single agricultural paper that is taken in this county. The zeal with which agricultural schools are urged, and legislative aid invoked, is certainly commendable, as it appears to me that that course will be the surest way of introducing the new system, as it is very hard to get men advanced in years and fixed habits to change. Our system of farming in this state, is certainly very bad, and I can see it more plainly since I read the Cultivator; (I have the back volumes.) To speak in general terms, we are carrying on the "skinning" system in high perfection. Our farms are mostly divided into "meadow and plough lands." As to permanent pasture land, we have very little; our cattle, sheep and hogs mostly run at large in the woods and old fields in summer. We alternate corn with small grain and small grain with corn; pasture our lands every opportunity, as soon as the crop is off, until we are ready to put another on. Clover is scarcely known here as a field crop, and as to stocking down our plough lands with grass seeds for mowing or pasture, the practice is not known here. Root culture is not attended to, but for the table. I have some doubts whether our climate is not too hot to pursue it to advantage. We go over a great many acres, and get few bushels; feed our stock from stacks in the fields, and "summer yard" what little manure is accidentally made about the barn and stables, and there is very little improvement in the breeds of our stock.—To all of which, however, there are some exceptions, particularly in this county; we have some enterprizing men who are departing from the beaten track, and endeavoring to improve their lands and stock; but so far as I am able to judge, we all lack knowledge as to the "why and the wherefore," or the true science of farming; but from the number of agricultural publications now in circulation, enough may be obtained to better our condition very much, and I feel a hope that proper exertions on the part of those who see and feel the necessity of a change, will bring about a favorable one, even among those who are fixed in the habits of their forefathers. As some evidence of my industry in the cause, enclosed are ten dollars for ten copies of the present volume of the Cultivator, for my neighbors who have consented to take them. And I would say to every subscriber, try and do likewise. Very respectfully, &c.

C. HARBIN.

Inquiry as to the Operation of Gypsum.

Canton, Pa. Dec. 1838.

Permit me to inquire through the columns of your very valuable paper, for a little information on a subject that would seem to merit more attention than it has as yet perhaps received from philosophic investigation; I mean the manner in which gypsum (common plaster) operates on plants to increase their growth. Does the sulphate of lime absorb another portion of oxygen from the atmosphere when on the blade of the plant, and thus leave the nitrogen at liberty to be absorbed by the plant to increase its growth, or is it some other way, or how is it? C. C.

Remark—The first point to be solved is, does the gypsum actually benefit the plant, *while upon its leaves?*—This is a controverted point—and we are rather inclined to sustain the negative. Our opinion is, that gypsum, that is, sulphuric acid in its combined state with the calcareous base, is a necessary element in all plants which it benefits, and that it is imbibed only by the roots of the plants from the soil, and consequently that it only benefits when it enters the soil. We know of no case where a greater portion of oxygen can be combined with sulphur than exists in sulphuric acid.—*Conductor.*

Singular Facts.

Black Locust Grove, near Liberty, Mo. Nov. 6, 1838.

Hon. J. Buel—Sir—In the last number of the Cultivator, I saw the rust on wheat attempted to be accounted for. Now, sir, I will give you my own observations and experience on that subject, for your reflection.

In the year 1835, the army worm, (a brown worm with white stripes,) made its appearance in Mason county, Ky. and was very destructive on some meadows and pastures, and some of us thought they would ruin our wheat, but not so. The season was wet and cool about the time of and during their appearance. The wheat had began to turn a little just below the head; a Major Waddle had two fields of wheat, one of them the worms stripped of all its fodder or blades, and got a few paces into the other, when they disappeared; the field they stripped made an excellent crop, while that portion of the other which they did not touch, was nearly ruined by rust. The fields were both clover sod, consequently the wheat rank and thick bladed. It was remarked that year, that every field in which the worms made their appearance turned off good crops, while most of those that escaped the worm were lost by rust, especially the fields that had been in grass.

Now, sir, you can make what use of this you deem best. I will now give you a description of some singular stocks of corn which made their appearance in mine and one of my neighbor's fields; the variety planted was the large yellow gourd seed. After the crop had generally silked, and the most of it in good roasting ears, you could see several stocks not tasselled, and still growing in all the thriftiness and verdure of June, though unusually dry. One of them (which I now have) is indeed a curiosity, measuring 17½ feet long with five joints undeveloped, (for there were five blades clustered up around the tassel, which had just began to make its appearance,) now allow only six inches to the joint, and it would have measured when grown, 20 feet, and 33 joints, 13 of which had roots from one to three inches long sticking out all around them; the blades were from four to six inches wide; none of the stocks ever had any corn on them. Most respectfully, AUGUSTUS H. F. PAYNE.

EXTRACTS.

Of Grass Lands that ought not to be broken up by the Plough.

There are various sorts of grass lands that ought not to be broken up; as water meadows; salt-marshes; lands apt to be overflowed; lands near large populous towns, where the produce of grass land is always in demand, and consequently dear; and low lying tracts, in the vallies of mountainous countries. But whether rich lands, which have long remained in grass, and continue productive, should ever be converted into tillage, is a question respecting which a great diversity of opinion has been entertained.

The lands considered as best adapted for permanent pasture, are of three kinds; strong tenacious clays, unfit for turnips or barley, which are said to improve more the longer they are kept under a judicious system in grass; soft clayey loams, with a clayey or marly bottom or substratum; and, rich sound deep-soiled land, or vale land, enriched at the expense of the higher grounds, generally lying in a situation favorable with respect to climate.

The advantages of such pasture are represented in the strongest light. It is affirmed that they feed cattle to a greater weight; that they are not so easily scorched by the summer's drought; that the grasses are more nutritive for both sheep and cattle; that milch cows fed upon them give better milk, and more butter and cheese; that the hoofs of all animals pastured on them are much better preserved; that they produce a greater variety of grasses; that when properly laid down they yield a succession of pasture throughout the whole season; that the herbage is sweeter, and more easily digested, and that they return an immense produce at a trifling expense.

To break up lands possessing these advantages, it is said, can only be justified by the most urgent public necessity, and to prevent the horrors of famine. The real value of such lands will appear by considering their rent and produce. The grass lands of Lincolnshire are accounted the best in the kingdom. The rents are various, from £1 15s. to £3 per acre, [equal to $7.77 to $13.32] and the value of the produce per acre from £10 to £15. This produce arises from beef, mutton and wool, and is obtained, with little variation from the nature of the seasons, and at a trifling expense. The stock maintained per acre on the best grazing lands, surpasses what could be fed by any arable produce. It is not at all uncommon to feed at the rate of from six to seven sheep in summer, and about two sheep in winter. The sheep, when put upon the grass, may weigh from 18 to 20 lbs. per quarter, and the increase would be at the rate of 4 lbs. per quarter per sheep. But suppose it only 100 lbs. at 8d. per pound, that would amount to £3 17s. 10d. The wool would be worth about two guineas more, besides the value of the winter keep, and the total may be stated at about £7 per acre, got at little expense. Such lands, it is evident, can not be better employed than in feeding stock.

Grass on tenacious clays and heavy loams, when brought in a succession of years, or perhaps of ages, into a state of great productiveness, can not be ploughed without the risk of great injury, and are more profitable in the production of herbage than they could be in the production of grain.

Grass on deep-soiled sound vale lands, would be productive of corn if ploughed; but would be probably injured by cultivation; from their texture being altered and rendered unduly loose and open by tillage; from the native plants being more or less destroyed or enfeebled; and from the great decomposition and waste of the principles of fertility resident in the soil.

The extent of these descriptions of land, however, is not so great, that the advantages of breaking them up could probably ever be a national object, or worth the risk of injuring their future productiveness in grass. But there are pasture lands of the inferior sort, which are apt to be confounded with those already described, and respecting the propriety of occasionally appropriating them to arable culture, there can hardly be a doubt. Such lands do not depend upon their intrinsic fertility, but upon annual supplies of manure derived from the arable land in their neighborhood.—*Loudon.*

OF THE ADVANTAGES AND DISADVANTAGES OF BREAKING UP GRASS LANDS.

The advantages of breaking up grass lands, not of the richest quality, will appear by a comparison of their product with that of arable land. From the inquiry of the Board of Agriculture, it appears that an acre of clover, tares, rape, potatoes, turnips, kale or cabbages, will furnish at least thrice as much food as the same acre would have done had it remained in pasture of a medium quality; and consequently, that the same extent of land would maintain at least as much stock as when in grass, besides producing every other year a valuable crop of corn; and this, independently of the value of the straw, which, whether consumed as litter, or as food for cattle, will add considerably to the stock of manure. It follows, that with the exception of rich pastures, arable land is, on an average, superior to grass land with respect to furnishing articles of human food, in the proportion of three to one; and consequently every piece of land, unnecessarily kept in grass, the produce of which will only maintain one person, is depriving the community of food, capable of maintaining two additional members.

The principal objection to the conversion of old turf into arable land, arises from an alledged infirmity in the new when compared to the old herbage; a complaint which probably originates either from the improper choice of seeds, or from giving them in too small quantities, thus favoring the growth of weeds. A gentleman who had a large farm, principally consisting of strong rich clay, (every field of which, with hardly an exception, he occasionally broke up,) was accustomed to lay them down with a crop of barley, and to sow 14 lbs. of white clover, a peck of ribbon grass and three quarters of hay seeds the acre. By this liberal allowance of seed, he always secured a thick crop of herbage the first year, which differed from old pasture only in being more luxuriant. Such lands, therefore, under judicious management, will rarely be injured by the plough. When laid down from tillage into grass, they may not carry for the first year or two, such heavy cattle as they would afterwards, but they will support more in number, though of a smaller size, and bring a greater weight of butcher's meat to market. It is often desirable to keep one or two moderate sized enclosures, of from ten to twenty acres, according to the size of the farm, in perennial pasture, for the feeding of cattle and sheep, and as a resort for the stock to go to in case of a severe spring, or summer drought; but the retaining of any considerable portion of a farm in old turf, or permanent pasture, unless of the richest quality, is, in general, injurious to the landlord, the tenant, and the public. The value of any estate, where the system of permanent pasture has been carried to an unreasonable extent, may be easily and greatly augmented by appropriating the manure of the farm to turnips and other green crops, and by the adoption of the convertible system of husbandry.

There are many cases where this doctrine, though in general to be recommended, ought not to be carried to its full extent. In Norfolk, where the land is commonly light, and where sheep are both bred and fed upon the same farm, a proportion of permanent pasture is essential.—*Loudon.*

[*From the (London) Farmers' Magazine.*]

Essay upon the Breeding of Live Stock, and on the Comparative Influence of the Male and Female Parents in Impressing the Offspring.

By John Boswell, Esq. of Balmuto and Kingcausie.

[In the year 1825, the Highland Society proposed as the subject of prize essays, the solution of the question, "Whether the breed of live stock connected with agriculture be susceptible of the greatest improvement, from the qualities conspicuous in the male, or from those conspicuous in the female parent?" Four essays were received, to which premiums were awarded. Those that were written by J. Boswell, Esq. of Balmuto, and by the late Rev. Mr. Berry, were considered the best. As many persons may not have seen these essays, which contain information valuable to all those who study the principles of breeding, we have given the essay by Mr. Boswell, which will be found interesting to every one concerned in the breeding of stock.]

Te quoque, magna Pales, et te memorande canemus
Pastor ab Amphryso.—VIRGIL.

The very great utility of a clear knowledge as to the best method of improving the breed of live stock, connected with agriculture, must be apparent to all; and as one heartily devoted to agriculture in all its branches, I cannot help congratulating the farmer on the information he is likely to receive on so important a subject through the endeavors of the Highland Society. As this subject has long (I may say from my earliest youth) been one in which I have taken the greatest delight, and on which I have bestowed much thought, besides having had very great opportunies of seeing experimentally the changes produced on stock from crossing, and other circumstances, I trust I may be justified from any charge of self-assurance, in offering a few facts in as short and succinct a manner as the nature of the subject and my own experience as an author, will permit, being well aware that facility of communicating knowledge is almost as necessary as experience in order to shine as an essayest.

Hoping, then, for candor in weighing the various facts I shall bring forward, and deprecating criticism as to the manner in which they are brought together (being a mere farmer, and no author,) I shall lay before the society such as occur to my recollection.

The society has put the question, "Whether the breed of live stock, connected with agriculture, be susceptible of the greatest improvement from the qualities conspicuous in the male, or those conspicuous in the female parent?"

The first thing to be done is to answer the query put by the society, and, having done so, to prove by facts that the answer given is the proper one. I have not the slightest doubt in my own mind that the answer ought to be "the male."* But before proceeding to prove this, I would warn all who may turn their thoughts to the subject, that it must be an enlarged view of this or any other matter connected with nature, which alone can give a true knowledge as to the point at issue. The fable of the fly on the building ought never to be forgotten; and the stock of a country or a district can only lead to the true result as to any particular breed. I would also remark, that, before the breed of a country can be improved, much more must be looked to than the answer to the question put by the Highland Society, such as crossing, selection of both parents, attention to pedigree, and lastly, food and care of the offspring.

I shall endeavor to explain my ideas on these heads; and then, having given some proofs as to the male being the parent having the greatest influence on the progeny, I shall endeavor to prove, that, whether I be right or wrong, still the male is the parent which we must look to, as best calculated to improve the breed of any country.

The art of improving the breeds of different animals was almost, if not altogether, unkown to the ancients. Virgil, who seems to have paid some attention to it, has stated things which experience has since taught us are erroneous. In this part of the island it has yet to be introduced, and we are forced to go to England for authorities on the subject. A few of our countrymen have indeed, of late years, come forth, as it were—and in this number we must rank Mr. Stirling of Keir, Mr. Robinson of Ladykirk, and Mr. Rennie junior, of Phantassie, who having seen the value of improved stock, and of attending to pedigree, or breeding from parents, "de bonne race," as the French well express it: but with the exception of these, and some few others, we are yet miserably behind. The very term "a great breeder," signifies two totally different things in England and Scotland: in the former, it means a judge, and one who delights in improved breeds; in the latter, a person who has a great number of (commonly speaking) half-starved calves or miserable lambs, and in whose stock we may see every variety of shape and colour. We have only to look to any drove of Scotch beasts on the road, to satisfy ourselves of the want of all care in our breeders. The cattle are of all different shapes, some with horns, and some without; and if you inquire of the owner, you will find that he purchased some of those dissimilar beasts, not from different breeders, not in different districts, but from the *same farmer*—and his own cattle in one fair. How and why is this? Because our Scotch farmer is ignorant of his own trade! They all know and admit, that "breeding-in-and-in," or "oure sib,"* as they call it, is bad; they know the value of crossing, and they wish to cross, and do so; but it is without judgment. A farmer no sooner hears that his neighbor has got a good bull, most likely from a distance, than he says, "I must have a breed of him," as he calls the first offspring between his own cow and this bull; and the cow is put to this animal, although the one should be Galloway, and the other a short-horn: thus his calves are so unlike, that, when his stock is carried to market, they present that tag-rag appearance which I have mentioned before, and which the best dealers are now rectifying to themselves for their own profit, by carefully classing them into horned or polled, &c. and thereby raising the value of the *self-same animal* from 10s. to 20s. a-head in the markets of the south, by giving them that uniformity which the breeder ought to have done.

When I would praise the advantage of crossing, I would have it then to be clearly understood, that it is only to bring together animals, *not nearly related*, but always of the same breed, never attempting to breed from a race-horse and a cart-mare, or *vice versa*. Such a thing may do well enough for once to get an insulated animal, but will end in vexation, if attempted to be prolonged into a line.

We know that crossing, even however ill-done, is productive of good. It uniformly frees an animal from many of the weaknesses and maladies to which those bred *in and in* are subject, and almost invariably procures a much larger animal than either of the parents. That enlightened gentleman and accurate observer of everything connected with animals, Sir John Sebright, whom I shall frequently have occasion to quote, says, "I have tried many experiments by breeding in and in, upon dogs, fowls, and pigeons; the dogs become, from strong spaniels, weak and diminutive lap dogs; the fowls become long in the legs, small in the body, and bad breeders."

Mr. Bakewell, that illustrious breeder, denied this; and was the first, I believe, who said that a cross was unnecessary, that animals would not degenerate by being bred in-and-in, &c. but let us look to the result. His admirable breed of sheep are fast going to decay; they have even now become small, and are, to a great degree, what is termed soft sheep, *i. e.* liable to many complaints. The malady to which sheep are most subject, decay of the liver, attacks them very frequently, and altogether, they make good the old adage, of soon ripe soon rotten; more quickly coming to maturity than any animal we know, and as speedily going to decay. I have seen the wonderful effects produced by crossing, in renovating this breed, having, for several years, been in the habit of buying in a couple of scores of Highland ewes, and putting them to a pure Bakewell ram. They were always poor small things, worth not more than from 3s. or 3s. 6d. to 6s. each; yet these ewes produced lambs which astonished every one who saw them, and which sold to the butcher at 10s. 6d. a head. As to the appearance of those lambs I shall have occasion to speak in another place. Did the limits of an essay permit I could bring many more instances to prove this my first position, that it is absolutely necessary to shun breeding in-and-in; but, as I must hasten to the main question, I shall only remark, that the benefit of crossing extends even to the vegetable creation, a fact which is now pretty well known, and may easily be proved in the cultivation of various plants. In none is it more conspicuous than in the turnip. It is now some years since it occurred to Mr. Gordon, farmer, at Orrock, near Aberdeen, that, as the brassica tribe easily breed together, as it were, it might be possible to cross the ruta baga with some of the other sorts. He did so, and found that the crosses which he had got were far superior in size to either of the sorts he put together, and also very hardy as to standing frost. I know another small farmer, who, after a very severe winter, tried putting red-top and Norfolk white turnips together, which are both very easily destroyed by frost. From these he procured a cross which stood the frost uncommonly well, and grew to a large size on poor soil. But to proceed to selection.

In this term I would include, not only the choice of two well-made parents, but the guarding carefully that the same defects, however slight, did not occur in both; for it is a fact, stated by Sir John Sebright, and which has uniformly been proved by my own experience, that it is not always by putting the best male to the best female that the best produce will be obtained; for should they both have a *tendency* to the same defect, although, in ever so slight a degree, it will, in general, preponderate so much in the produce as to render it of little value.

I found the truth of this in a very striking instance about ten years ago. Having a cart mare of a very superior description (and which has twice gained premiums at agricultural shows) I looked out for a first-rate stallion, intending to breed from her. At that time a horse, belonging to Mr. Buchan, near Crief, called Blaize, was carrying all before him.* I thought I could not do better than breed from this horse, not taking into consideration that both sire and dam were of the same make, viz. rather long in the leg; the consequence was, that I had a very fine foal to be sure, but with longer legs than either of the parents. The next time I had learned to correct my former error, and bred from a short-legged horse from Cheshire, which was a great cross to my Scotch mare, and also differed from her in shape. The effect was immediately visible. I had a mare which it would be difficult to produce an equal to, the leg not being so short as the father's, although the whole appearance much resembled him, nor quite so long as that of the dam. Another very striking instance of this came under my notice a few years ago. A friend of mine (General Burnett) had a mare what is called three parts bred, certainly a very fine mare to breed from, but a very tall mare, with long legs, which was put to the longest legged thorough-bred horse I ever saw (Bethlem Gober, the property of lord Aboyne.) The produce quite resembled the sire, and, at two years old, had reached the height of seventeen hands; but he was a monster, all legs, and very soon proved this by knuckling over at the pastern joint, till at last he could not walk; and at three years old was shot. The same mare was next covered by Hospitality, a horse as remarkable for being short in the leg, and what is termed short-jointed. The produce was now a low sturdy animal, greatly resembling the sire, and short in the leg;† thus in both instances proving, not only what I mention to be requisite, viz. judicious selection of the two parents in reference to the make of each, but also the great power of the male to change the whole shape and appearance of the produce.

I proceed next to mention the necessity of attending to *pedigree*.

If we look, with an attentive eye, to Nature and to her productions, we shall see that they are not only beautiful, but that all she does is uniform. Thus, every wild animal is of the same colour, and nearly of the same shape; every flower resembles another; but man must always be assisting nature, as he terms it. Then we see flowers grow many coloured, or perhaps double; beasts and birds change their shape, colour aud nature, so that we see such varieties as were altogether unlooked for.

The only way we can guard against this, is to know well what the *ancestors* of the animals we breed from were. Without this, our produce will every now and then be breaking through the general rules, and annoying us with odd-looking animals, deriving their shape from some of their ancestors, perhaps, two or three generations back.

Few words will suffice as to food, and care of the offspring. Nothing can be more absurd than to suppose that animals can improve if neglected in their youth.

We have the strongest proof of this in the starved animals brought from the West Highlands, which crowd our fairs, particularly those of Falkirk and Hallow Fair of Edinburgh. Let a farmer buy some of those when "year olds," and place them (ere they be at the age of maturity) in a more genial climate, and on good keep. See what beautiful cattle they become. Let him buy two-year olds, and the improvement will be less—at three, and they will only lay on fat, without reaching large size. On the other hand, let him purchase half a dozen starved looking small cows, from the same part of the country, in calf (provided they shall be of the pure breed;) let him take those cows home, and suffer the produce to suckle the dam while she feeds in good pasture. In winter, let them be well fed, and lie in a shed or house tolerably warm. What sort of beast has he now? Let the reader call to mind the West Highlanders shown at Queensbury House for the two last years, every one of which weighed from 70 to 80 stone, and the question is answered. I was once taken to see the cattle of the late General Simpson, who had the purest short-horn blood, a breed which, without all doubt, are capable of being made the fattest. These cattle were in such a state as I have never seen any other animals. They were all bone and skin, their eyes looked unhealthy; and altogether, from starvation, and I rather think from want of crossing, they appeared like so many invalids in the last stage of consumption. To improve any breed, or keep it up when improved, stock must be well fed from the time they are produced. "Sir," said a great breeder to me once, "to produce a fine animal, you must feed him from the starting-post." Warmth, that is a temperate climate, appears to be perfectly necessary to the improvement of all animals, and particularly so *in live stock connected with agriculture;* for, if we look at these animals, or even the human species, whether in the frigid or in the torrid zone, we find them dwindling into Liliputian size.

---

* It often happens that an author who has distinctly espoused one side in a question so difficult as this, feels disposed, after the lapse of two or three years, to modify, or even alter, his opinions; but it is consistent with our knowledge, that the accurate observations and farther experience of two years have only strengthened the author of this essay in the assertions which it contains.—*Editor Farmers' Magazine.*

* Nearly related.

* This horse generally cleared £150 per annum to his owner, gaining every prize at all the agricultural shows for many years; frequently being selected as the best, when 25 to 30 of the finest stallions from Clydesdale and Fife were shewn in the same field; and was, without all doubt, a most superb horse.

† In the Philosophical Transactions for 1809, in a paper by Mr. Knight, on the same subject as this essay, the author, in contending for the impropriety of propagating from large in preference to small females, brings forward a very interesting remark upon length of leg in the offspring. "Nature," says he, "has given to the offspring of many animals (those of the sheep, the cow, and the mare, afford familiar examples) the power, at an early age to accompany their parents in flight; and legs of such animals are nearly of the same length at the birth as when they have attained their perfect growth." The natural result from which would be, that the offspring should resemble their mother in length of leg, and consequently, while there was an excess in this respect on her part, care ought to be taken to breed from a male, calculated by the comparative shortness of his legs, or the great depth of his chest and shoulders, either to correct the tendency or impart a body of proportional power.—*Ed. Mag.*

I come now to the grand point; to prove which, I conceive it will be necessary to fix upon some marks whereby a change, and that change an improvement, may be traced. The one, which in my mind is by far the strongest, is colour; next, I would place smallness of the head and ears; in the horse, ox, and sheep, prominence of the eye; in all wideness of the chest, tendency to fatten, early maturity, tranquillity, and love to man, or rather dependance on man.

Let us now proceed regularly, and commence with the horse, as the most noble as well as the most useful animal. The influence that the male has on this class of animals is the most striking. Every one must recollect how, in blood-horses, the colour of the sire goes throughout the progeny, and, in a dealer's stable, every grey is a Delphini or a Sir Harry Dinsdale, every black a Sorcerer or a Thunderbolt, and so on. While you hear people constantly remark that such a horse can be nothing but a get of such a one—what is this but to say, the colour and appearance of the male goes throughout the produce? In work-horses it is the same. A very strong instance of this was visible some years ago in the county of Kincardine. Here there was not, I suppose, one single mare to be found of a chesnut colour, when Mr. Barclay, of Ury, brought down a Suffolk punch, of a bright red chesnut colour, and in a few years plenty of chesnuts were to be found. A few years afterwards, a dun or slate-coloured stallion gained the prize from the Kincardine Agricultural Association; when he came into the country, dun horses were very rare, now they are to be found everywhere. In the county of Fife, some years ago, a horse called Sportsman, found his way from Yorkshire, and covered a vast number of mares, particularly those belonging to the farmers, which at that time were either black or grey. This horse was a rich dark brown, with a tanned muzzle, and he instantly made a very large proportion of horses of that favorite colour; and what is still more remarkable, he was himself one of the best trotters ever seen, and his progeny were so also, so that the farmers talking of a good trotter, would say, "O yes, he is a Sportsman." Sir Robert Dick, a few years ago, purchased a work-mare, which I happened to know the breed of for several generations. She was black, very large, and coarse; eyes small, head and ears large, and very rough at the heels. This mare was put to Caleb Quotem, a beautiful bay horse, with much of what dealers call gaiety. I saw the produce; it was bright bay, with no hair at the heels, the eyes large, the head and ears small, and altogether the produce had put on the appearance of a blood-horse. Here the dam was of the cart breed. Let us look the other way: Mr. George Harley Drummond had two or three thorough-bred mares, which had thrown foals, small in size and deficient in bone to a blood-horse. He put them to a cart-horse, they instantly produced stout boned colts, with much hair at heel, and altogether like the sire. In the year 1821, I purchased a very neat small mare for a relation of mine, which had a foal at her foot by a cart-horse; this foal turned out to all intents a very good cart-horse. The mare was afterwards put for three seasons to Kutuzof, and the foals were in all appearance like blood-horses.

The late General Ayton, of Inchdairnie, a great many years ago, sent down a horse from England to his property in Fife, which covered the country mares in his vicinity (at that time, I am informed, very poor beasts,) and produced such wonderful effects on the breed in that neighborhood, as may be seen this very day; the horses in that quarter being the best in the country, and particularly remarkable for width of chest, docility in work, and altogether fine animals. Last year (1824) I chanced to see the tenantry of a gentleman, who has the district which lies along the banks of the river Avon, in Aberdeenshire, driving his winter store of coals. The horses struck me as being far above the common run of those in the Highland glens, and in fact first rate, compared with what ten years before I had seen in the carts of the self-same farmers. I was at first somewhat at a loss to find out how so great a change had taken place, as I knew that the land in that part of the county was all held by small farmers, who neither could nor would purchase large high priced mares to breed from, far less those horses then in my view. I soon found, on investigating the matter, that the whole change had been brought about by good stallions; and in this way: The different agricultural associations in the north have, for many years, been in the practice of offering large premiums for stallions, which brought troops of fine horses from the west of Scotland. After the best had been picked out for the prize, the rest were set adrift; and these horses, dispersed over the country, of late years, from the badness of the times and an overstock of them, covered at any price the farmer pleased to offer. Thus good horses wandered into their glen, to their very doors, and at such a price as these men could give; the result was what I have stated.

In the horse, then, it seems clear that it is to the *male* we must look for improvement. Not that I would be supposed to assert that the whole improvement can be brought about *at once* by the male; that, if a man were to put a Shetland pony to Eclipse—such a one, for example, as "The Great Unknown" has been pleased to mount Mr. Yellowlees on—were the little beast, from which the agriculturists' legs dangled, put, I say, to Eclipse, no one would hope to procure a racer; nor can we think that a Lincolnshire black, and a Highland garron, taken out of a peat cart, will produce an animal fit for a London dray; but by repetition the end will be produced. I once put the question of the Highland Society to a very able man who fills a chair in one of our universities, and who is an observer of nature of no ordinary cast, and who also, from his profession, (a medical man,) may be supposed to be a good judge. His answer instantly was, "The male, without all doubt, but (added he) you must have a female capable of developing the good properties of the male, otherwise a good male will be thrown away."

(*Remainder in our next.*)

On the best means of permanently improving the class of Clay Soils.

[*From the Farmers' Magazine.*]

There is no doubt but thin clay soils could be easily improved, and perhaps in a much greater degree than the sandy soils have been during the last 40 years; and the surface may yet be seen clothed with a rich herbage which shall vie with that of the other soils in producing the best cheese, beef, and mutton.

Clay soils, will produce pasture just in proportion to the quantity of decaying active vegetable matter in their composition. If this be abundant, the crop will be rich and luxuriant; and the decaying fibrous roots will form a dry, porous soil, giving a sufficient depth for the rain to sink through the subsoil, where it will run off by the furrow drains. If there be little vegetable matter in the soil, the moisture will make the earthy matter in it collapse and adhere together; and it will form a cold, wet, sterile clay, producing little else but carnation grass of little value.

Pasture on clay soils should never be converted into arable culture, unless the application of skill and capital will not only repay the additional expense of the culture, but also tend to increase the permanent productiveness of the soil. Without a proper application of skill, capital and industry on such land, the converting it into arable culture will only tend to diminish the produce, if the free produce under the artificial culture fall short of that which nature itself afforded.

Much may be learned from the practice of market gardeners, in the neighborhood of London and elsewhere. They have two methods of trenching their land When the soil and subsoil are good to a great depth, they turn the surface under and fetch up a fresh spit from below to constitute the surface for so many years; but when the subsoil is poor or strong clay, they bastardtrench it, as they call it; that is, they throw the surface spit forward, always keeping it uppermost, and dig the subsoil by turning it over in the trench without moving it from its place.

Their object in thus trenching their clay soils is to get depth for the rain-water to decend, and to give a greater depth of moisture to the roots of plants in dry weather, and for the superabundant moisture in wet weather to decend below the roots of plants, and run off to the drain.

If we perfectly drain thin clay soil by furrow draining, and deepen the subsoil by trenching with the spade or the subsoil plough, making it pervious to the moisture which falls on it, that it may immediately sink to a depth below the reach of the roots of the plants, the cultivated surface will be dry; and if we reduce the tenacity of the soil by applying to it those light or sandy substances, which, when well incorporated with it, will make and keep the soil permanently porous and friable, then the land which before produced only a poor crop of carnation grass, or if arable, of oats, will now produce an abundant crop of wheat, beans, oats, clover, and even turnips; and if properly laid down, and full of manure, will form a rich pasturage for any kind of stock.

When clay soils have dry pervious subsoils, they become darker in colour from the repeated application of manures, and under a proper system of cultivation they lose their adhesiveness, and become a loamy soil, producing the most fruitful crops of wheat, beans, clover, vetches, cabbage, and naturally produce the best and richest herbage for dairy cows. The milk from cows fed on such pasture produces more cheese and butter than the milk of cows fed on a sandy soil, and of a better quality.

Any thing which will produce permanent friability in clay soils, such as sand, lime, burnt clay, loose light vegetable matter, or long unfermented manure, will alter its texture and improve its quality.

When tenacious soils are completely subsoil drained, and a system of deep or subsoil ploughing is adopted, every time when the land is in summer fallow, if the soil be deepened and the subsoil made more porous; and if never ploughed when too wet, and a full portion of vegetable manure be given to the soil, and well mixed with it, a mechanical effect will be produced, which will change the nature and texture of the soil, and give to it that friability which is so essential in all productive soils. The rain that falls on it will now percolate through it to the depth of the new formed subsoil, and thence to the furrow drains.

The soil now receives the circulation of the air, which is carried on by the rains filling up the interstices which the air previously occupied, and the complete drainage draws off all the superabundant water as it falls. By this operation the earth again receives a fresh supply of air from the atmosphere, which promotes a chemical as well as mechanical action in the soil, and hastens the decomposition of the air and water, as well as the vegetable and animal manure it contains, and thus a liberal supply of the nourishment necessary for the growth of plants is obtained.

Soil that is principally composed of calcareous matter, in minute divisions, becomes a most tenacious stubborn soil; and, under certain circumstances, as sterile as the most worthless clay. Calcareous matter, therefore, although reckoned a valuable constituent in a soil, becomes an evil when it composes the greater part of it.

Calcareous clay, when thoroughly dried, falls to pieces like burnt lime, whenever it is again wetted.—Every poor clay soil may be much improved by paring and burning the surface, after it has been completely drained.

This is the first step that ought to be taken towards ameliorating such a soil, and the more clayey the soil is, the deeper ought the soil to be burnt. When the burnt surface is mixed with the soil to the depth of the furrow, it acts as a coarse sand, and makes it more friable and porous, by converting the matter, which was before damp and adhesive, into a dry, friable, warm soil, permanently improved and capable of producing luxuriant crops of every kind.

If we can get depth and friability to the subsoil of strong adhesive clay we thereby prevent stagnant water from injuring the roots, and give to the plants the liberty of sending these roots to a greater depth in search of nourishment.

In all rich soils, there is vegetable matter in every state of decay, and the greater this portion of decaying vegetable matter is in strong clay soils, the greater is its productive powers. Besides this, decomposing vegetable matter will tend to keep strong clay land loose, friable, and porous.

Cash Book.

[*From the Farmers' Cabinet.*]

A little care prevents much cost and trouble.

It is a very easy and simple affair to keep a cash book, and yet how very few farmers do it. Any person who can write can keep a book of this description, and many advantages accrue from it. On one page of your cash book set down every thing sold, and the sum received for it. On the other side put down all your outgoings or expenditures; and when it is begun, if the amount of cash on hand is put at the top of the column of receipts, at any time by adding up the two pages, and taking the difference of them, will show the balance of cash you should have in hand; and if there is any disagreement, there must be some error of entry, or there must be "a hole in the purse." A book of this kind accurately kept, would show at the end of the year, or at any other time, the amount of wheat, corn, potatoes, butter, poultry, eggs, or any other articles sold and the sum received for them. It would do more, it would show all your outlayings for stock, seeds, implements of husbandry, repairs, clothing, tea, coffee, sugar, salt, &c. &c. and also for wages, and would present a very curious and interesting document for family examination at the end of a twelve month; and if there should be found to be "a hole in the purse," it would indicate the spot where repairs were most necessary.

A farmer keeping a book of entries of this description, would always know his latitude and longitude, as a captain of a ship does when on the ocean, and he would be less likely to run on to shoals, or get among the *breakers*. As it is not very usual among farmers to take recepts when money is paid on ordinary occasions, and not in very large sums, and as the memories of many people are very frail, such a book of entries as has been referred to, would be of essential service as a record of payment when no other evidence of it existed, and might prevent litigation and trouble in case of the decease of one or both of the parties. On the death of the head of a family who has kept no regular records of his receipts and payments, much difficulty and sometimes heavy losses have occurred, besides a great deal of trouble and anxiety to those who were obliged to grope in the dark in settling his estate.

It is well known that very many worthy intelligent farmers are careful to preserve an accurate statement of all their worldly concerns, duly arranged in proper form, and such rarely find "a hole in the purse."

But there are many others who would at once plead guilty, or, if they did not, could readily be convicted on responsible testimony, of totally neglecting to keep any intelligible series of entries in a book, of their ingoings and outgoings, and these are the persons who often complain of "a hole in the purse," and yet they are not careful to have it repaired in due season.

ABRAHAM.

System of Culture.

In every system, it is absolutely necessary to attend to the equal distribution of labor throughout the year; so that the work which the system requires to be performed in each month may be easily accomplished by the means the farmer is provided with. The different operations should never be allowed to encroach on each other. If these are properly adjusted, the business of each week will be confined to the time in which it is required to be performed.

The best mode of cultivating arable land is that which produces the greatest quantity of green food for sheep and other beasts, and which they should eat on the ground.

This prepares the land for a crop of grain or corn for the use of man. The alternate system of grain and green food for stock, is that which never should be deviated from.

It produces not only a much greater return of corn and other food for the use of man, but also a much greater quantity of green food and straw which sheep and other animals consume, and gives at the same time a proportionally greater return of vegetable and animal manure. By this means the farmer has not only the power of reproducing the same quantity of grain, &c. but of increasing the capability of the soil to produce an additional quantity. The production of turnips and green food for sheep, gives perhaps ten times the quantity of manure, that the old system did. Increased productiveness given to the soil is genuine agricultural improvement.

Crops of corn, as food for man, alternating with crops of vegetables, as food for sheep or other stock, is the foundation of all good husbandry.

Such a mode of culture should be adopted as will not only increase the quantity of manure, but hasten its decomposition, and thus increase the productiveness of the soil by raising an increased quantity of food for sheep to be again consumed on the land that produced it; and when the soil is thin, poor, light sand, this may be repeated year after year, on the same land, whether it be arable or pasture. The consumption of the produce by sheep on the land is the best, the cheapest, and the most effectual means of improving pasture, as well as arable land.

Vetches, rye, clover, and buckwheat, are sometimes grown on land and ploughed in as a manure; but if these crops were converted into a manure by passing them through the stomach of sheep, the effects produced would not only be much quicker, but of much greater value.

When the farmer is convinced that his corn crops are productive just in proportion to the quantity of sheep he keeps on his arable land; and when he is experienced in the best mode of cultivating the varieties of grain and vegetables which are best adapted to the soil of his farm, he may then calculate with certainty on the result of his operations.

As the weeds which grow on the land are the natural plants of the soil, they much sooner feel the influence of the weather, the manure, and the culture, than the artificial crops we cultivate, and consequently take the lead of the crop; we ought therefore to eradicate every weed out of the land, and when once we get it clean, to keep it so.

We should never take a crop of corn, if by taking it, we give an opportunity for the weeds to spring up in the soil; for this would be only sowing the seeds of future labor and expense, as well as incur loss to us in preventing their increase. The repetition of corn crops in succession tends to increase the stock of weeds in the soil, without giving to the farmer either the time or the power to diminish them, and their growth necessarily retards or prevents the growth of the crop we cultivate; but the production of green crops, such as turnips, potatoes, vetches, and clover, gives to the farmer time and power to clean out any weeds that may be in the soil; and the growth of these crops prepares the land for the production of a crop of corn.

It should be remembered, however, that whenever the weeds have got ahead of us, we must then have recourse to summer fallow to get rid of them. Whatever gives nourishment and life to weeds would, if no weeds were in the ground, give life and nourishment to cultivated plants; and that land which has a dry porous subsoil is most productive, and much easier cultivated than that which has a retentive subsoil; therefore if the land have not a porous dry subsoil naturally, one should be given to it artificially, and this the farmer should do whatever be the expense,—it will repay him with compound interest.

Different modes of culture must be adopted on different soils; for it is evident that the same cause will have very different effects upon soils of a different nature.

The effect produced by rain on clay soils has been shown to be very different from the effect which it produces on sandy soils; and the effect of drought on a dry sandy soil is equally different from the effect which it has on a wet clay soil.

Frost expands the water in the soil about one-twelfth; hence during a thaw, the water is contracted to its original bulk, leaving the soil in a loose open state, and well prepared to receive the influence of the atmosphere. Sandy soils are easily penetrated by water and air; but clay, unless well pulverized, is impenetrable to either.

The best soil for any kind of plant is that in which it naturally grows with most luxuriance; and a quicker repetition of such plants may be made than of those to which the soil is not naturally so well adapted.

Clay soils having a proper mixture of sand and lime will produce wheat, beans, clover, and cabbages, in the greatest perfection.

Light sandy loam is best fitted for the production of barley, rye, peas, turnips, potatoes, vetches, &c.

Every different soil requires a peculiar management, and a different course of cropping.

Light sand and gravel are early soils, and should be early planted in the spring, that their growth may shut out the influence of the sun from the ground at an early period of the summer.

All succulent plants, and those that are not allowed to ripen their seed; such as clover, rye grass, vetches, turnips, cabbages, carrots, potatoes, &c. are said to receive a great part of their nourishment from the atmosphere; and therefore do less injury to the land than wheat, barley, rye, oats, peas, beans, or any of the succulent plants when they are allowed to bring their seeds to perfection.

Vetches, peas, and beans, seem only to injure the land they grow on when they are permitted to perfect their seed; for if they grow so luxuriantly as to produce nothing but straw, which is sometimes the case, or if, like vetches they be cut green, their growth does not injure the land but is an advantage to it; we may therefore presume that it is only in ripening the seed that the soil is injured by such crops.

When clover, vetches, turnips, cabbages, &c. are produced and consumed on the land without perfecting their seed, the soil is not at all injured by their production, and they may be repeated and consumed every year not only without the least injury being sustained by the soil, but an actual yearly increase is thereby made to its productive powers; if any one of these crops, however, be allowed to perfect its seed for two consecutive years on the same soil, the land would be injured for many years to come. The inference to be drawn from this fact is, that the soil is injured more in producing the seed, than in producing the stem and foliage, or leaves. The foliage may receive more of its nourishment from the air than the seeds; or, the seeds may receive more of their nourishment from the soil than the foliage.

The injury that land sustains from converting grass into hay is, that the production of seed either of grass or of corn is that which injures the land more than the most luxuriant growth of leaves or straw.

Pasture prevents the production of seeds and encourages the growth of the roots, which are thus promoted, and are constantly pushing out in search of nourishment all the year round; so that there is no period when they lie dormant, as in the case when seed is produced.

All perennial plants that produce seed lie dormant for several months after they have produced it; and annual plants, if prevented from yielding their seed, either by mowing or pasturing, become biennial or even triennial.

There is a great loss sustained by land from the keeping of corn in the straw for a year or two; as the farmer is thereby prevented from keeping stock to consume the straw, and of course the land sustains the loss of manure from its non-consumption.

The adoption of the best rotation of crops will not secure, at all times and under all circumstances, the improved result: no! the rotation must be accompanied with the most sedulous attention to the minute details of all the operations, and these must be executed at the proper time to insure the result required.—*Morton on Soils.*

Young Men's Department.

Hints to Young Farmers.—No. XII.

SOCIAL AND CIVIL DUTIES.

Every person of common reflection must be aware, that he owes to others, and to society, certain social and civil duties, in requital for the kind offices and protection which he receives and enjoys from the community of which he is a member; and he *should* know, for such we consider to be the indisputable fact, that upon the manner in which these duties are performed, will materially depend his reputation with good men, and the measure of his pure enjoyments in life. Hence it is of the first importance, that he should fix upon a scale of morals in early life, which shall govern in his business transactions, and in his intercourse with society.

Every class in society seems to have a scale of morals peculiar to itself, in its business affairs, none of which are exactly fitted for general adoption. The importing merchant, for instance, thinks it justifiable to use deceptive invoices, by which he defrauds the revenue of a part of the duties due upon merchandize; while the salesman is valued and rewarded according to his tact in extolling his wares to the buyer—in giving them a fictitious value. Those who subsist on the spoils of office, consider that—"all is fair in politics"—that "the end justifies the means." The lawyer encourages litigation, because it is his vocation—his dependence for the wants and the superfluities of life. The physician knows when he gets hold of a rich patient, and deems it no breach of morals to make him pay well—to pay something for his poor neighbor. The parson, even, feels no compunction in abandoning his flock to the wolves, and *accepting a higher salary*, when he is persuaded he can be more eminently useful to the cause of vital piety. And the farmer practices a thousand little devices, to multiply his pence, which he would hardly applaud in his neighbor. We do not mean to charge these practices upon the whole of the different professions—for there are many honorable exceptions in all—we would merely intimate that they are besetting sins, human propensities which it requires fixed principles and inflexible fortitude to resist and overcome. If once successfully indulged in, they are apt to obtain an ascendancy; and to become more and more difficult of restraint.

But there is a precept, of the highest authority, applicable to all classes and conditions of life—which all commend, though few practise it. It is to "DO UNTO OTHERS WHAT YOU WOULD THAT THEY SHOULD DO UNTO YOU." This constitutes the highest rule of moral conduct, and its observance confers the highest honor—the purest happiness. Adopt it as the rule of life. It will insure you the respect and love of all who cherish virtue—it will do more—it will insure self-approbation, and self-respect.

Order and Neatness;

OR THE FORCE OF INDIVIDUAL EXAMPLE.

[*From Fireside Education*]

These two virtues generally go together, and you seldom see one without the other. In illustration of their benefits on the one hand, and the evils which result from their neglect on the other, let me introduce to the notice of the reader the following sketches, which he may have seen before. They are pictures of village life, but lessons may be drawn from them to suit the city, as well as the farm-house and cottage.

The village of Decay is situated somewhere in New-England. The land is good, and the people have all the means of comfort and happiness, but they don't know exactly how to use them. We shall give a sketch of Capt. Seth Wideopen's house, which is a sample of the whole town. Capt. Wideopen, by the way, is a good sort of man enough, and is well off, as the saying goes. He has two hundred acres of land; but he has not the good sense to observe the advice of the old rhymes—

"'Tis folly in the extreme to till
Extensive fields, and till them ill.
The farmer, pleased, may boast aloud
His bushels sown, his acres ploughed,
And, pleased, indulge the cheering hope
That time will bring a plenteous crop.
Shrewd common sense sits laughing by,
And sees his hopes abortive die,
For, when maturing seasons smile,
Thin sheaves shall disappoint his toil.
Advised, this empty pride expel;
Till little, and that little well.
Of taxing, fencing, toil, no more
Your ground requires when rich than poor;
And more one fertile acre yields
Than the huge breadth of barren fields."

The captain is also ignorant of the advantages to be found in following the injunctions laid down by the same writer, as follows:—

"Neat be your farms: 'tis long confessed
The neatest farmers are the best.
Each bog and marsh, industrious, drain,
Nor let vile balks deform the plain
No bushes on your headlands grow
Nor briers a sloven's culture show.
Neat be your barns, your houses neat,
Your doors be clean, your court-yards sweet;
No moss the sheltering roof enshroud,
No wooden panes the window cloud,
No filthy kennels foully flow,
Nor weeds with rankling poison grow;
But shades expand, and fruit-trees bloom,
And flowering shrubs exhale perfume.
With pales your garden circle round;
Defend, enrich, and clean the ground;
Prize high this pleasing, useful rood,
And fill with vegetable good."

The fact is that there is more comfort in neatness and order than most people think of. There is also much virtue in these things. They stamp themselves, after long habit, on the mind and heart, and, to some extent, mould the intellectual and moral character. No being but a pig is happy and at ease in the midst of filth and confusion; and if a person, by living among them for a long time, gets reconciled to them, he is so far depraved and degraded toward the standard of one of the lowest of the brute creation.

But to be a little more particular. Capt. Wideopen's house stands on a broad street that runs for a mile in length through the village of Decay. It is an old farm-house, one story high, with its gable end to the street. In front of the house is the wood-pile, spread out so as to cover a rood of ground. As you pass by, the barn, cow-house and yard, with its deep morass of manure in high flavor, salute the eye and nose. The pig pen, wide open and in full view, is between the house and barn. In a warm day the congregation of vapors is overwhelming. The well, the wash-shed, the wood-shed, all are in full view to the passers by. The space around the front door is defiled by the pigs, who root and grunt there by day, and by the geese, who roost there by night.

Thus all the unsightly and unseemly objects are spread out to view, and the scene is embellished by the addition of broken sleighs, sleds, ploughs, wagons, carts, old posts, &c. There lies a shapeless heap of stones; yonder is a gate hanging by one hinge, which will soon be broken for want of care. Here is a pair of bars thrown down; there the stone wall has tumbled over!

Such is the scene presented by the residence of a wealthy, respectable farmer in New-England; and I am sorry to say that there are hundreds, nay thousands, like it in New-England—ay, in New-England! Not that every village is a Decay, or every farmer a Wideopen. No! Some of our villages are delightful, and some of our country people are patterns of good order and neatness. But I am speaking of those who are not so. And if these pages should come into the hands of any person, in New-England or out of it, who is ignorant of the advantages of neatness and order, let me urge upon him, as worthy of immediate attention, the following remarks, drawn from observation and experience.

1. A man, whose house, like Capt. Wideopen's, is out-of-doors marked by disorder, confusion and want of cleanliness, is generally the same in-doors.

2. Where there is confusion and want of neatness, though there may be plenty of bread, butter, milk, cheese, fuel, clothing and other necessaries, there is little comfort, little thrift, little good nature, little kindness, little religion, little beauty, little peace or happiness.

3. Children brought up in the midst of confusion and want of cleanliness, are likely to be low, vulgar and vicious in their tastes and in their character. Let fathers and mothers consider that, if they bring up their children in this way, they are schooling them to be drunkards, profane, mean, base, wicked and despised; that the schooling of home is the most lasting of all schooling; that the ferule of the school-master cannot efface what the father and mother have taught; that the preacher cannot destroy the die stamped upon the young heart at home by parental example! Look to this, ye fathers and mothers, and if for your own sakes ye are indifferent to neatness and order, for the sake of the young immediately around you, be no longer so!

4. There is a constant tendency in the want of order and neatness to cause ruin and waste; consequently a man who, like Capt. Wideopen, allows things to go on in this way, generally gets poorer and poorer, till at length, mortgages, embarrassment, debt, losses and the law, bring him to poverty.

5. Neatness and good order contribute to health, wealth and happiness; while opposite habits tend to disease, misery, poverty, vice and short life.

Let us now turn to another scene. The village of Thrivewell is also a New-England village, and is remarkable for its pleasant, cheerful aspect. Every person who rides through it is delighted; and the place has such a reputation, that the land is worth more, and the houses will sell for more, than in almost any other place of the kind you can name. And this arises from the good taste, neatness and order, which characterize the inhabitants. I will give you a sketch of the house belonging to Capt. John Pepperidge; a careful, correct, upright man, who has risen from poverty, to ease and competence, by industry, economy and prudence.

His house stands three or four rods back from the street; the front yard is green, grassy and decorated with handsome trees. The wood-pile is fenced in; the barn-yard, pig-pen, &c. are also tidily fenced. It is a favorite proverb with Pepperidge, that there *should be a place for every thing, and that every thing should be in its place.* This is his great maxim; and he not only observes it himself, but he requires every man, woman and child about him to observe it also. He says it saves him one hundred dollars a year.

He has other rules, such as *a stitch in time saves nine*: thus, as soon as a stone falls off the wall, he puts it up; when a rail gets out of the fence, he replaces it; when a gate is broken, it is forthwith repaired; if a clapboard is loose, a nail clenches it. Thus, matters are kept tight and tidy. Of a wet day, instead of going to the tavern, he spends the time in making little repairs. At odd moments of leisure, he sets out trees and shrubs; thus, year by year, beautifying his place, and rendering it not only more comfortable, but also worth more money, in case he should ever desire to sell it.

Capt. Pepperidge takes great pleasure, and perhaps a little innocent pride, in his place, though, to say the truth, it is by no means costly. He loves better to spend his time in making it more convenient and pleasant, in setting out trees, improving the grounds, mending the fences, &c. than in going about to talk politics, or gossip upon other people's business, or in haunting a tavern bar-room. In short, his home is comfortable, pleasant, delightful. It is neat and orderly, inside and out. And he has made it so; though his wife, having happily caught the influence of his example, contributes her share to the good work. His children are well dressed, well educated, well behaved. Can such a man be a drunkard? Can he be vicious? Can he be wicked? Who has so good a chance of health, wealth and happiness? Who so likely to be respected by his neighbors? Who so likely to do good by his influence and example? Come, Capt. Wideopen, I pray you, and learn a lesson of farmer Pepperidge!

Let us look at the practical effect of Pepperidge's example. Formerly the village of Thrivewell was called Uneasy Swamp, and was inhabited by a set of people becoming the name. They were poor, ignorant, idle and *uneasy*. They were jealous of all rich people, and considered the unequal distribution of property a dreadful evil. They were equally jealous of the wise, and considered the unequal distribution of knowledge a nuisance to be abated. They were also jealous of the virtuous, and hated nothing so much as a just and honest man.—In short, they were, half a century ago, where some conceited but ignorant and ill-minded people are now, willing to level every body and thing to their own standard. If a candidate for office was up, who addressed their prejudices, and coaxed them with promises, though meaning to cheat them, he was the man for them. If he was known to be mean, slippery and unprincipled, fellow-feeling seemed to render them kind, and the more ardently they espoused his cause. Such was Uneasy Swamp; a place which may have its image still in some parts of the country.

But Pepperidge came among the people and set them a good example. They persecuted him, reviled him, hated him, ridiculed him, broke down his fences at night, and played him sundry mischievous tricks. But he was patient, and tough in his patience, as the tree that gave him a name; and he overcame them at last. One by one, the villagers began to imitate him. The small brown houses gradually lost their look of squalidness and disorder. The Swamp emerged from its shadow, and became a cultivated valley. The little farmers and the humble mechanics rose from their degraded condition; education spread its light; industry and frugality showered down their blessings; and Uneasy Swamp became the flourishing village of Thrivewell.

And thus, though none of the people are what is called rich, none are poor. The small houses are neat, and the fruit-trees, the blossoming shrubs, the green grass around them declare that the people are happy. They are not mad in the foolish chase for riches, which is destroying more peace in this country than all the bodily diseases our flesh is heir to. They are now, from better knowledge, satisfied that the rich man shall possess his wealth, both because they perceive that, generally speaking, the laboring classes are the happiest, and that the security of property is the only steady impulse to economy, industry, providence, and the other important village virtues. They are more fond of knowledge, for they perceive that it increases their power of being happy. They respect talent and wisdom, for they know that these are gifts sent by heaven for the guidance of man to happiness. In politics, they are staunch republicans, but always give their votes for men of sterling integrity. A man who has the general character of being an artful, intriguing office-seeker, has no chance with them. They are perhaps a little prejudiced against cities and city people. If they ever have any thing to do with a lawyer, they go to one who has been bred in the country, and one who was in early life a farmer.—They think, and, perhaps, justly, that while this rustic breeding gives a man an habitually honest and plain turn of mind, it also renders him more knowing, sagacious and favorable in his feelings, in respect to country people.

I cannot better close this sketch than by introducing some lines which are much esteemed in the village of Thrivewell. Every man, woman and child there knows them by heart.

> " Let order o'er your time preside,
> And method all your business guide.
> Early begin and end your toil,
> Nor let great tasks your hands embroil;
> One thing at once be still begun,
> Contrived, resolved, pursued and done.
> Hire not for what yourselves can do,
> And send not when yourselves can go;
> Nor till to-morrow's light delay
> What might as well be done to-day.
> By steady efforts all men thrive,
> And long by moderate labor live;
> While eager toil and anxious care,
> Health, strength, and peace, and life impair.
>
> Nor think a life of toil severe;
> No life has blessings so sincere.
> Its meals so luscious, sleep so sweet,
> Such vigorous limbs, such health complete,
> No mind so active, brisk and gay,
> As his who toils the livelong day.
> A life of sloth drags hardly on;
> Suns set too late and rise too soon.
> Youth, manhood, age, all linger slow
> To him who nothing has to do.
> The drone, a nuisance to the hive,
> Stays, but can scarce be said to live;
> And well the bees, those judges wise,
> Plague, chase and sting him till he dies."

CASIMIR PERIER, on being called an "aristocrat," and one of the privileged classes, replied—"My only aristocracy is the superiority which industry, frugality, perseverance and intelligence will always assure to every man in a free state of society. I belong only to those privileged classes to which you may all belong in your turn. They are not privileges created *for* us, but created *by* us. Our wealth is our own; we have made it. Our ease is our own; we have gained it by the sweat of our brows, or by the labor of our minds. Our position in society is not conferred upon us, but purchased by ourselves—with our own intellect, application, zeal, patience and industry. If you remain inferior to us, it is because you have not the intellect or industry, the zeal or the sobriety, the patience or the application, necessary to your advancement. This is not our fault, but your own.—You wish to become rich, as some do to become wise; but there is no royal road to wealth any more than there is to knowledge. You sigh for the ease and repose of wealth, but you are not willing to do that which is necessary to procure them. The husbandman who will not till his ground shall reap nothing but thistles and briars. You think the commodities in human society are useless and misdirected if you do not become wealthy and powerful by the changes; but what right have you to expect—you idlers and drones in the hive—you shall always be fed on the honey and sweets of life? What right have you, who do nothing for yourselves, your families, your communes, your arrondissments, your country or your kind, to imagine that you will be selected by them for their favor, their confidence, their rewards?

"I am not an aristocrat in that sense of the term in which it may be applied in absolute governments, or under imperial rule; but if, by an aristocrat, you mean a man who has earned his promotion by his industry—Oh, then, indeed, I am an aristocrat; and, please God, I may always remain so. The distinctions in human society displease you, because you have not the talent or industry to amend your own position. You are too idle to labor, and too proud to beg; but I will endeavor to take care that you do not rob me. I throw back, then, with indignation and resentment, the charge which is made. I belong to the middling classes of society. I have been selected by my fellow citizens, and by my king, as one of their representatives; and, by the blessing of God, I WILL REPRESENT THEM."—*Blackwood.*

FROM THE STEAM PRESS OF
PACKARD, VAN BENTHUYSEN & Co.

THE CULTIVATOR:

A MONTHLY PUBLICATION, DEVOTED TO AGRICULTURE.

I KNOW OF NO PURSUIT IN WHICH MORE REAL AND IMPORTANT SERVICES CAN BE RENDERED TO ANY COUNTRY, THAN BY IMPROVING ITS AGRICULTURE.—*Wash.*

VOL. V. NO. 3, WASHINGTON-ST. ALBANY, N. Y. FEBRUARY, 1839. No. 12.

Conducted by J. BUEL, of Albany.

TERMS.—ONE DOLLAR per annum, to be paid in advance. Subscriptions to commence with a volume.

Special Agents.—L. & R. HILL, Richmond, Va.; BELL & ENTWISLE, Alexandria, D. C.; GIDEON B. SMITH, Baltimore, Md.; JUDAH DOBSON, bookseller, D. LANDRETH, and M. S. POWELL, seedsmen, Philadelphia; ISRAEL POST, bookseller, 88 Bowery, ALEX. SMITH, seedsman, P. WAKEMAN, office of the American Institute, Broadway, N. York; HOVEY & Co. Merchants' Row, Boston; ALEX. WALSH, Lansingburgh, and WM. THORBURN, Albany, gratuitous agents. For general list of agents see No. 12, vol. iv.

The Cultivator is subject to common newspaper postage.

☞ Price of the published volumes, 50 cents per vol. stitched—the four volumes bound together, $2.75—bound in two volumes, $3—the four vols. bound each separate, $3.25.

THE CULTIVATOR.

TO IMPROVE THE SOIL AND THE MIND.

☞ An extra sheet of 16 pages accompanies this No. making 32 pages gratuitous matter with this volume.

☞ A LIST OF AGENTS, principally of gentlemen who have volunteered as such, accompanies this number. ☞ Any person who forwards us Ten Dollars, for ten subscribers, becomes virtually an agent, and is entitled to the eleventh copy for his trouble, or to ten per cent, and in that proportion for any greater amount. Post-masters are particularly invited to receive subscriptions—a legitimate object of the post-office law being, in our opinion, to facilitate the diffusion of useful knowledge among the people.

☞ An interesting communication from Mr. Garnet, of Virginia, and several other favors of correspondents, are unavoidably postponed till our next.

Close of the Volume.

This No. closes the fifth volume of the Cultivator. We have endeavored to make it useful to the great cause of improvement which it professes to promote; and in this effort we have been ably sustained by more than TWO HUNDRED CORRESPONDENTS, from different parts of the Union. To these gentlemen both the Conductor and the Patrons of the Cultivator are under great obligations; and we feel warranted in tendering to them, in behalf of our subscribers as well as ourselves, our hearty thanks. But this, we trust, is but a small portion of their reward: the consciousness of doing good to others—of having discharged a high obligation to society—is the *best* reward to a philanthropic and benevolent mind. Who can pretend to limit the beneficial effects, present and remote, which will result to the nation from their concentrated labors—*to improve the soil and the mind!* We see every where the most salutary changes, in the improvement of our husbandry, and in the condition of farmers, produced by the increased circulation of agricultural periodicals; and yet, in our opinion, we see but the germ of their usefulness. And is there a member of society, be his situation what it may, that can say, *he* is not benefited by this change? Putting our own labors out of the question, is there a subscriber, who after attentively reading *this* number, will say, that he may not be benefited by the matter it contains—more than one dollar—the price of his annual subscription? We think not. These considerations, we trust, will stimulate our correspondents to persevere in their labors of usefulness. We have a stock of individual experience and useful knowledge in our country, which, if drawn out and diffused over the land, would cause it to teem with plenty.

We feel also under great obligations, and wish here to make our acknowledgments for them, to the numerous class of gentlemen who have volunteered as agents—from a wish to promote useful improvement—to extend the circulation of the Cultivator.—We earnestly invite a continuance of their co-operation.

Board of Agriculture.

In the bill reported to the last legislature, by Mr. L. F. Allen, for the improvement of agriculture, there is a provision for the establishment of a Board of Agriculture. The subject has been recommended, by the Governor, to the consideration of the legislature. Propositions for establishing similar boards in Virginia and North Carolina are now, we believe, before the legislatures of those states. The bill of Mr. Allen provided further, that a room in the new state buildings should be assigned for the use of the board, and that the room should also serve as an agricultural museum.

As both the board and the museum may appear of doubtful utility to many, we will endeavor to explain, as far as we are able, the objects of both,—or at least to suggest some of the advantages which may be expected to result from their establishment, sufficient, we think, to warrant any expenditure they may require from the state.

It is matter of general notoriety, that the agricultural staples of a district, or state, are subject to fluctuation and change. These changes arise from exhaustion of the soil for particular crops;—the introduction of new articles of culture;—the fluctuations of the market;—the demands for new and particular products, or from other unforeseen causes. We have witnessed many of these changes in our day; and unless we mistake the signs of the times, other changes of importance are on the eve of taking place, at least in many districts, by the extension of root culture, the silk business, and the fabrication of beet sugar. To facilitate these changes, which are often indispensable, it is important that our farmers should be early and correctly advised of the best modes of managing the new articles of culture, and of their products and profits. Thousands, and tens of thousands, may be wasted in useless experiments, and a useful and profitable branch of culture may get into disrepute and be neglected, for the want of the requisite knowledge for its management.

The upper valley of the Hudson, and the valley of the Mohawk, were, not very remotely, the great wheat growing districts of the north. Wheat was their staple product, and this wheat constituted the great mass of farm produce which was sent down the Hudson from this city and neighborhood to New-York. These districts do not now produce enough wheat for their own consumption. Wheat culture has given way to cattle and sheep husbandry, and to the raising of coarse grains.

The great staples of our southern states, a few years ago, were rice, indigo and naval stores. Cotton was then a stranger to their soil; but it is now almost their entire staple, and constitutes by far the largest article of export from the United States.

The New-England states formerly raised grain and provisions sufficient for their consumption, and to export. They are now importers to a large amount. Manufactured goods constitute their principal exports.

Root culture is but of comparative recent introduction into Great Britain. It has changed her whole system of husbandry, as that of the sugar beet has that of France. The advantages which have resulted to those countries, from root culture, have been vastly great; and New-York, we have no doubt, will ere long reap from it like advantages. We are now much in need of manual instructions for cultivating the beet, and manufacturing the sugar. The French farmers have been immensely profited by the exertions of their government to collect and diffuse a knowledge of the best modes of practice in the beet sugar business; and even now that government is offering large bounties for new improvements in the manufacturing processes. France now makes 100,000,000 lbs. beet sugar per annum.

The silk business is exciting great attention among us. Our soil and climate are adapted to it. Managed as a household concern, it promises to become a source of individual and national wealth. But we lack experience, and we lack instructions which may be implicitly followed. We import silk to the amount of 20,000,000 dollars a year, produced in a soil and climate very similar to our own. Under the instruction and fostering care of the government, the silk business might soon become a great and profitable one to New-York.

These two new branches of agricultural labor, the beet and the silk business, have already attracted the notice of adjoining states, whose legislatures have offered liberal bounties to encourage their prosecution. Connecticut gives a bounty of one dollar for every hundred mulberry trees planted in the state, for the fabrication of silk, and fifty cents per pound for every pound of merchantable silk made in the state. Massachusetts gives a bounty of one dollar for every ten pounds of cocoons produced, and one dollar for every pound of silk reeled or thrown in the state; and a liberal bounty on sugar manufactured from the beet root. Vermont gives a bounty of ten cents a pound on cocoons; and Pennsylvania and New-Jersey, we believe, have also offered bounties to encourage the silk business. New-York, no doubt, stands ready to follow the praise-worthy example of her sisters, in these as in other matters deeply interesting to her agriculture—as soon as she has settled the question of party ascendency. But hitherto her statesmen have been too much engaged in *political* legislation, involving banks, rail-roads and canals, to cast a thought upon the humble claims of agriculture; which, having had nothing to give to party, would of course be last to be served by party.

New grains, new grasses, new roots and plants, new breeds of animals, new implements of farming, new manures, and new modes of culture, are constantly coming into notice. Many of these would prove valuable in our husbandry. Our agricultural population are so dispersed, their means of information so limited, and they are withal so distrustful of whatever is new, that improvement with them progresses slow. But were there a central board, who would take early cognizance of these matters, and publish their opinions upon them; who would collect, at home and from abroad, all choice seeds that promise to become an acquisition to our husbandry, and distribute them among careful and discreet farmers, the progress of improvement would be greatly accelerated. In regard to new farming implements, there are and will be many of intrinsic merit—and there are and will be others that are worthless.—The farmer cannot distinguish well the good from the bad without trying them, and this he has seldom the opportunity of doing thoroughly. The consequence is, he is often deceived; and is afterwards deprived of the benefits of those which are good, from an honest distrust of his own judgment as to their merits. The matured opinions of competent judges, acting under the authority of the state, would go far to prevent imposition, and to facilitate the general introduction of the most valuable kinds.

There are already several articles in extensive use in our country, and for which the home demand must increase, which might be profitably cultivated among us, were their culture once fairly introduced, and the processes of preparing them properly taught.—We will particularize madder, woad and weld, plants in extensive use in dying cloths. We import annually of these to the value of some millions of dollars. We have grown them all on a limited scale, and have no doubt but they may be made profitable farm crops.

Having made these preliminary remarks, we are now prepared to answer the question—

In what way would a Board of Agriculture benefit the State?

A Board of Agriculture should consist of three or more intelligent men, and a secretary, meet perhaps quarter-yearly, and receive a fair compensation for the time necessarily devoted to the duties of their office. The secretary should devote his whole time, under the direction of the board, to the interests of agriculture—

1. In collecting, arranging and publishing statistical and other useful information in regard to rural affairs.

2. In collecting and distributing seeds of such kinds of agricultural products, as may promise to profit our husbandry; together with the modes of their culture, management and preparation for market.

3. In receiving, labelling and arranging, models of implements, geological specimens, seeds and samples of rare or excellent products of the soil, portraits of fine animals, donations of books, &c. and in exhibiting them to visitors, and explaining their objects, qualities and promised advantages.

4. In answering the inquiries of agricultural men, on all matters relating to any branch of husbandry, or any article of culture.

5. In corresponding with societies and individuals, on matters promotive of the interests of agriculture.

The due performance of the above enumerated duties could not fail to be very serviceable to the state, in promoting the improvement of her agriculture. But there are other duties which might be performed by the board, of unquestionable benefit, should one be instituted, and the legislature think proper to confide such to them, to wit:

6. Examining, testing and deciding upon the me-

rits of all new implements of husbandry, offered for their inspection—and upon which the board might be authorized to award discretionary premiums, where the articles should be judged highly meritorious—and thereby giving them a character upon which the public might rely. And,

Last in order, though perhaps first in importance, a Board of Agriculture might write, compile, or procure to be written, and printed, books upon agriculture, the veterinary art, orcharding, gardening, rural embellishment and household economy, suitable for the common school libraries of an agricultural population.

In the several duties above enumerated a Board of Agriculture would do much good. Such a board has been eminently useful in Great Britain. Such virtually, in France, is the Royal Central Society of Agriculture—its premiums, and its laboring members, being paid from the public treasury.

The great question with many will be,—not what will be its ultimate benefit—but *what will be the cost?* The man who plants an apple tree, does not expect an immediate return for his outlay. He knows that he has to wait years for his remuneration; but he knows it will come; and that when it *begins* to come it will go on progressively increasing in profit, till he has returned to him his fifty or his hundred fold. So it is with expenditures for improving agriculture; the returns, though not immediate, are progressive and certain. The cost of a Board of Agriculture, however, will depend much upon what they are allowed by law to expend. Their pay and expenses would probably not equal the pay of many individual inspectors and other officers under the government; and would hardly amount to a tenth of the expense wasted last winter, in the boyish struggle in our legislature—to get credit to *party* for a short session.

An agricultural museum would be a matter of no great expense, but one of manifest utility. It would be taken care of by the secretary, with perhaps occasional assistance. Geological specimens might be furnished from the collections made by our geological corps. Models of agricultural implements might be required from the patentees or proprietors who exhibit them for inspection. Books would accumulate as donations; and portraits of choice animals would be presented by breeders, as a matter of interest. Specimens of agricultural products, and seeds of rare vegetables, would be tendered by our farmers, from motives of pride as well as of public usefulness. Foreign seeds and agricultural curiosities would be collected by our citizens travelling abroad, and by those engaged in foreign commerce. Every citizen would feel disposed to add to the collection whatever might be useful or curious of the productions of the soil. The hall would become an agricultural news-room—a central point of resort for citizens and strangers, who wished to acquire information, or should be desirous to communicate it, on the all-important business of agriculture. It would also afford an appropriate place for lecturing upon practical agriculture; and upon the sciences connected with its improvement, in the winter months—subjects which may yet become as popular and useful as phrenology and animal magnetism.

The Highland Agricultural Society of Scotland, to which we may safely refer for models of usefulness, is erecting a magnificent hall, at an expense of nearly 30,000 dollars, to serve as an agricultural museum. In this are to be deposited models of all known agricultural implements and agricultural machinery—an assortment of seeds, grains and grasses adapted for British culture—specimens of various kinds of timbers produced by forest trees—a collection of insects and grubs known as inimical to trees and plants—samples of dyes derived from native shrubs, with specimens of shrubs themselves—specimens of minerals, ores and rocks existing in Scotland, and adapted for useful purposes—original maps and surveys, explaining the geological structure of different countries, and showing where coal, lime, iron, stone, and other valuable mineral products abound—models and portraits of different varieties of stock, of the most approved breeds, showing their respective points and characters, &c. &c. Such a museum, we believe no one will deny, would be of value to any state,

---

Gov. Seward's Message.

It is neither our province nor intention to take notice of this able state paper, further than it relates to education and to agriculture, two subjects which, however seldom associated in the public mind, are nevertheless intimately connected, in what best promotes the great interests of our republican institutions. Education in the higher branches of knowledge, including natural science, and the application of the principles of the latter to productive labor, would multiply the legitimate sources of our wealth, and raise the agricultural class, in intelligence and in spirit, to the elevated rank assigned to them in our political charter, and which the safety of the republic requires they should occupy. This class once enlightened, would know how to appreciate the advantages of education; and having the means and the disposition, would take care to provide liberally for the education of their children.

The governor well remarks, that crime decreases as useful knowledge is disseminated. There are abundant statistical facts, to verify this remark. By useful knowledge, we mean particularly, that knowledge which incites to, and augments the fruits of, productive industry—that knowledge which gives to the possessor ample power, not only reputably to provide for himself, but to administer to the wants of others, and to advance general improvement in the condition of the human family.

"The standard of education," says the Message, "ought to be elevated not merely to that which other states or nations have attained, but to that height which may be reached by cultivation of the intellectual powers, with all the facilities of modern improvements, during the entire period when the faculties are quick and active, the curiosity insatiable, the temper practicable, and the love of truth supreme. The ability to read and write, with the rudiments of arithmetic, generally constitute the learning acquired in common schools. To these our colleges and academies add *superficial instruction in the dead languages, without the philosophy of our own; scientific facts, without their causes; definitions, without practical application; the rules of rhetoric, without its spirit; and history, divested of its moral instructions.* It is enough to show the defectiveness of our entire system, that its pursuits are irksome to all except the few endowed with peculiar genius and fervor to become the guides of the human mind, and that it fails to inspire either a love of science or passion for literature.

"Science is nothing else than a disclosure of the bounties the Creator has bestowed to promote the happiness of man, and a discovery of the laws by which mind and matter are controlled for that benignant end. Literature has no other object than to relieve our cares and elevate our virtues. That the pursuits of either should require monastic seclusion, or be enforced by pains and penalties upon reluctant minds, is inconsistent with the generous purposes of both. Society cannot be justly censured for indifference to education, when those who enjoy its precious advantages manifest so little of the enthusiasm it ought to inspire. All the associations of the youthful mind, in the acquisition of useful knowledge, must be cheerful; its truths should be presented in their native beauty and in their natural order; the laws it reveals should be illustrated always by their benevolent adaptation to the happiness of mankind; and the utility and beauty of what is already known should incite to the endless investigation of what remains concealed. If education could be conducted upon principles like these, the attainments of our collegiate instruction might become the ordinary acquirement in our common schools; and our academies and colleges would be continually enjoying new revelations of that philosophy which enlightens the way, and attaining higher perfection in the arts which alleviate the cares of human life."

We are here urged to raise the standard of education; we are admonished of the insufficiency of our colleges and academies in teaching what is most useful in the important business affairs of life; and we are told, that under a proper system of education, all the useful attainments of college instruction, might become the ordinary acquirement in our common schools.

The great source of the evil here complained of, we apprehend, is to be found in a vitiated public taste, formed too much after the fashion of the old continent—a predilection for what is showy, and superficial and transitory—in preference to that which is useful and substantial. With us, "merit should make the man, and want of it the fellow." Yet such is the homage we are accustomed to pay to a fine exterior, to polished manners, and to professional and mercantile pursuits, that the farmer or mechanic, seeks these professions and employments for his son, as the surest means of giving him fame and fortune, and in the hope, too, often, of sharing himself in the anticipated distinction of the boy. Hence, in subserviency to the public taste, is the inutility of our higher schools of instruction to the useful branches of industry. "I am ashamed," says Prof. Gordon, of Clinton College, "that so little of our boasted learning is practical—tamed—domesticated, and familiarized to the avocations of men.—When the young man graduates with honor, he is then unfit for any occupation—he has still to learn his profession. Whereas, the college, or university, ought to fit young men at once for the occupations they are to follow." The plan of the professor might be carried out, with facility, in the great business of agriculture, and the time and expense of the noviciate of life greatly lessened. A school of agriculture would teach his head knowledge, and his hands labor, at the same time, without impairing the value of either branch of instruction. Give him the "scientific facts" of the college, and he would explain "their causes," and demonstrate their effects and their utility in *field practice.* Give him the literary polish of the higher schools, and you would fit him for the civil duties of life. And give him, superadded to his scientific and literary teachings, a practical knowledge of the best modes of farming, and he comes forth from the school, highly qualified for usefulness—for *head*-work or *hand*-work, conjointly or separately. He will have no occasion to be ashamed of his profession, or to seek the bar or the counter, or to peddle pills or politics, to become respectable and respected.

"We seem at last," says Gov. Seward, "to have ascertained the only practicable manner of introducing normal schools into our country. It is by engrafting that system upon our academies."

We are sorry to question the correctness of this conclusion. We are afraid that but few, very few, of the young men who are participating in the public bounty in our academies, will be disposed to follow the humble business of teaching, longer than to acquire the means, or until an opportunity presents, of embarking in a more lucrative employment. The academy is considered a sort of stepping stone to the liberal professions; and we doubt whether those who are set apart for teachers can divest themselves of the predilections of the school.

We have another cause of doubt. From the character his excellency has given us of our academic studies, we are obliged to doubt the competency of these normal schools to qualify teachers for instructing a rural—an agricultural population. We beg not to be misunderstood. Academies may be considered purely literary institutions. They teach little more than ordinary schools, that concerns rural economy, or the arts of productive labor. Now it is a conceded truth, that boys should be taught what they are to practice when men. A vast portion of our male children are destined for agriculture and the arts, and under proper teachers, might acquire much elementary knowledge in their future business. Will the pupils from our existing normal schools possess either the disposition or ability to impart to them this preliminary, but very useful instruction? So far as our knowledge goes, no normal schools have yet proved successful, but such as have been exclusively devoted to the instruction of teachers; and in most cases where they have proved successful, we believe, the pupils have been instructed, in a greater or less degree, in the principles and practice of agriculture—qualifications considered useful, if not essential, in the teachers of a rural population. Normal, like agricultural instruction, holds but a secondary grade, when connected with literary schools; and the inferior will always be made subservient to the higher study.

The allusion, in the message, to the promised utility of common school libraries, is forcible and concise; and we hope the request to the legislature, to give its "co-operation in the *beginning* of this wise and momentous policy," will be promptly complied with.

"For the evil of our whole system," concludes Gov. S. on this subject, "there is a remedy, simple, economical and effectual—the establishment of a department of education, to be constituted of a superintendent appointed by the legislature, and a board to be composed of delegates from subordinate boards of education to be established in the several counties. The state board might exercise a general supervision, with powers of visitation of the colleges, and the county boards the same powers in their respective counties. The duties of all these officers, except the superintendent, ought to be discharged without compensation, and the tenure of office might be made so long as to secure efficiency. I am satisfied the state abounds with competent individuals who would assume those duties without other remuneration than the consciousness of rendering enlightened and patriotic service in the cause of education."

Boards of Education have been established in some of the neighboring states, and the one in Massachusetts, in particular, has already had a highly salutary influence towards improving her system of public education.

We extract below all of the message which relates directly to agriculture, and shall reserve our remarks upon it to a future occasion. It forcibly impresses upon the consideration of the legislature, the importance of providing for the improvement of this primary, but too much neglected art.

"The science which involves the physical laws most open to our investigation, and to which the primeval law of our existence compels us, and the art which precedes all other inventions, and whose cultivation leads to plenty, and is cheered by health and contentment, are the last which receive the patronage of phylosophy, or attain the favor of government. Mankind learned the distances and laws of planets, and even the periods of comets, before they conceived the mysteries of vegetation; and the fine arts were perfected in ages when agriculture, loaded with the superstition of centuries, was consigned to slaves. That this should have been the experience of other ages and other countries is easily explained. The powers of government have always been vested in classes or individuals farthest removed from the tillers of the soil; and ambition and pride have sought gratification in conquests and in the homage of the fine arts. But it must not, it cannot be so here, where the agricultural interest is sovereign, and as it furnishes all the means, rightfully supplies the motives, and directs the action of the government.

"Every acre of cultivated land could be made to yield, with the expense now bestowed upon it, products exceeding by one-third in quantity and value of its present fruits. The diffusion among the cultivators of the earth of the science belonging to their art would enlighten their minds, enlarge their views, elevate their motives, and refine their sentiments. Let it be remembered, that all this is necessary if we would not see the power residing with them steal away, as has always before been the case, to other classes, whose pursuits secure intellectual cultivation and superior wealth. Agriculture appeals to us as republicans, therefore, with peculiar earnestness, not only by our desire to increase the public wealth, enlarge the public intelligence, and elevate the standard of public virtue; but as we would preserve the ascendency of that policy of peace and improvement identified with the existence of democratic institutions.

"Among the plans of improvement which have been suggested, is the formation of a Board of Agriculture. I respectfully commend it to your favorable attention. Such a board might be usefully employed in introducing new species and varieties of productions, and improvements in implements of husbandry, and in carrying on a general correspondence with a view to promote the interests of agriculture.

I submit also whether it would not be well to require that a popular treatise upon agriculture should be contained in the district school libraries; and whether legislative sanction and patronage could not be so extended as to encourage the organization of agricultural societies, free from the defects which have hitherto proved fatal to their permanency and success."

Prof. Shepherd's Horticultural Address.

We have been kindly furnished with a copy of the address of Prof. Shepherd, delivered before the Horticultural Society of New-Haven in Sept. last, and have read it with great pleasure. It inculcates not only greater attention to the fruit and kitchen garden, as highly conducive to health and comfort, but it urges the culture of flowers, and the planting of ornamental shrubs and trees, as sources of intellectual pleasure, and as means of improving the public taste and promoting rural embellishment.

"The supply of fine vegetables, for the every day supply of the table," the Professor justly remarks, "has not yet received, in our country, all the attention it deserves. The people are every where too much engrossed by what they believe more pressing objects than the raising of vegetables. The farmer is too apt to sacrifice his garden to his staple crops. It is only after his heavy planting is finished, that he finds time to throw in his early crop of garden seeds; and these, when up, receive no care, except at odd moments, and on rainy days. Few vegetables with him, therefore, attain perfection; and these only when circumstances happen to prove propitious. The mechanic, the tradesman, and the professional man of villages and smaller towns, where garden spots are within the means of every person, bestow but little more attention than the farmer upon the culture of vegetables. The kinds produced, the modes of cultivation, and the quantity of supply, each admit of great improvement."

We believe but few persons, who have ever enjoyed the fruits and comforts of a good garden, are willing to forego them, or are apt to remit in their culture. In this respect, a taste for gardening is much like a taste for reading—the more it is cultivated, the more interesting it becomes, the more it grows upon us. The great point, in both, is to begin—to taste,—to realize the pleasures and the profits which they confer. If the farmer, or the village cit, would but *begin*, properly, to cultivate the garden, and persevere through one season, we might count upon his progressive improvement. But if the ground is but half prepared, a circumstance which often occurs, the seeds put in late, and the culture neglected, the product will consequently be trivial, and the quality inferior; and it is no wonder that the owner considers the garden unworthy his care, or meriting only his secondary consideration. In the garden, as on the farm, things should be done in time, and well done—"a stitch in time saves nine:" an *hour* spent in destroying *small* weeds, will often go as far as a *day* spent in destroying *large* ones; and the crop, if timely cleaned and thinned, may give a liberal reward to labor, while if left crowded, and choked with weeds, may fall far short of it. We pledge our belief, that if the farmer of occasional leisure, the mechanic, or the professional gentleman, be he even the clergyman, will spend one half of the time he can spare from his business, in the practical business of the garden, for one season, he will find his health improved, his mind enlarged, and the rational pleasures of life much increased. To the young, a taste for gardening may avert many evils, and lead to much positive good; to the middle aged, it will be a source of high intellectual enjoyment; and to the aged it will afford a healthful exercise to the body, and a pleasant recreation, without alloy, to the mind.

In its bearing upon health, which we all ought to cherish as one of the first blessings of life, the garden and its products, in the opinion of the Professor, have a benign influence.

"It is conceded," says he, "by those who express opinions upon the science of *hygiene* in the United States, that the very free use of animal food is a vice in the dietetics of our people. The fact I hold to be intimately connected with the poverty of our gardens. I do not indeed deny, that our supply of the cerelia is often inadequate; but bread, though called the staff of life, is not intended to be the sole vegetable accompaniment of our meals. Man cannot live by bread alone; and if you deprive him of other varieties of vegetable diet, he will inevitably indulge to excess in the use of animal food. In order to preserve that due adjustment of the vegetable to the animal diet, intended for us by nature, it is not enough to give him, along with the potatoe, an occasional taste of the common sorts of the leguminous and cruciform families of vegetables, but the variety must constantly be rendered as complete as possible, embracing productions the most widely asunder in flavor, as well as in the quality of nutricious matter which they contain."

Perhaps there are no people in the world, who consume so large a proportion of meat with their daily food, as the people of the United States—and very much, we believe, to the prejudice of their health. The mass of the population of Asia, as also of middle Africa, and of middle and southern Europe, subsist almost entirely upon vegetable diet. An erroneous opinion is entertained by many, that a great portion of meat is necessary to the laboring man.—And why? Not because meat affords the most nutriment. According to Vauquelin and other eminent chemists, as quoted in the Encyclopædia Americana, meat contains far less nutriment than many vegetable substances. One hundred pounds of bread is said to contain 80 lbs. of nutritious matter; 100 lbs. of peas 93 of nutrient matter; 100 lbs. of beans 92; and 100 lbs. of meat but 35 lbs. of nutrient matter; while the potatoe affords of nutrient matter 25 per cent. Thus showing that three pounds of potatoes are more nutricious than two pounds of flesh.

The Professor not only complains of the small proportion of vegetable food which we consume, but of the injudicious mode of preparing it for the table.

"Increased attention," says he, "must likewise be devoted to the preparation of vegetables for the table, which subject, I think, comes in (appendix-wise if you please,) among the objects of our society; and particularly recommends itself to the regard of those ladies of the association who occupy the very honorable station of heads of families. Already several delicious vegetables are becoming common in our gardens, which nevertheless but rarely find their way to the table, or when there, are found unpalatable, solely from defective modes of cooking.

"I trust, therefore, that one good result of our society will be the proper regulation of diet; for it appears to me, that well cultivated kitchen gardens and fruit yards are much more likely to effect the object, than the wisest dietetic rules, or the most stirring lectures, in the absence of such necessary provisions."

In speaking of the peach, Prof. S. says, "it is only necessary to plant the trees in a *deep rich soil*, where they will enjoy a shelter from cold winds, and to prune them *annually*, with a *bold hand*, in order to secure a constant and abundant crop." This location for the peach, with us, we should consider a very bad one, as the growth would not cease so early, nor the wood consequently ripen so well before winter, as on a light dry soil, and in a more unprotected situation. Nor can we agree with the Professor in recommending the pruning knife to be used *annually*, and with a *bold hand*, upon standard trees. The branches may be cut in to a thrifty sprout, after having fruited two or three seasons, but we believe the policy of close pruning, and especially of cutting young healthy laterals, has been thought wrong by professional gardners.

In recommending the cultivation of flowers, and ornamental trees and shrubs, Prof. S. pertinently asks—

"Need I speak of the inducement to cultivate such plants within and about our houses! While their delicious odors regale our senses, their form and beauty may be said to improve our taste. The inspection of [exotic] plants, so dissimilar to our native productions, is calculated to awaken in the minds of the young a curiosity in favor of botany; a science whose study has been found to be highly propetitious to early mental culture, —operating as it does to sharpen the habits of observation, to promote discrimination, and to impart, in a remarkable degree, the perception and love of order."

The Professor recommends, particularly, an attention to the domestication and culture of indigenous plants, and ornamental shrubs and trees, of which we can boast of many that are truly beautiful; he enumerates a great number of this description; directs the mode of mixing and grouping them; and recommends planting not only in door-yards, and in streets, but the vacant grounds in the neighborhood of the city. He complains of the neglect of the apple orchards, which have either disappeared, or exhibit a melancholy emblem of neglected old age. Without at all interfering with the temperance cause, the apple orchard is now found to be a valuable appendage to the farm. Giving a succession of fruit during the whole year for the dessert and kitchen, it is capable of contributing largely to the sustenance of the family; while every kind of farm stock, it is now satisfactorily shown, may be fed and fattened upon the fruit with economy and profit.

The Professor dwells with minuteness upon the policy of beautifying the streets and public grounds with ornamental trees, and he forcibly illustrates this policy, by referring to the monuments of past ages—the stately elms which embellish the college green, and which have been the admiration of all strangers who have visited New-Haven. The circumference of some of these trees is said to be from 12 to 18½ feet. One of them was planted by the Rev. James Pierpont in 1688. An interesting fact is also stated, viz: that five generations ago, the parishioners joined their gifts to erect for their pastor a dwelling.—One poor individual, who had no other offering to give, brought from the woods an elm tree, and planted it before the door of the parsonage. The last vestige of the mansion has been devoured by time, and the liberality of those who built it forgotten, while the tree lives and towers in majesty, promising to carry down to other generations the name of William Cooper, the poor man who plucked it from the forest, and planted it where it stands.

Hints for the Master.

Hay that is made in the shade retains its colour and its sweetness much longer than that which is made in the sun, but it requires a longer time to dry. * * * I have found hay which has been made in the shade, after being exposed to the free action of the air for three months, smell as sweet as on the day when the mass from which it was taken was stacked—*Smith on Improved Agriculture.* These remarks go to corroborate what we have often stated, that hay cured in cock, is much superior to that cured by being spread to the sun.

The same writer suggests, that fodder may be greatly augmented by mixing the hay from the field with dry straw in the mow or stack; and that where this is to take place, the hay may be housed much greener than otherwise. The straw is enriched by the surplus juices of the grass. We have practised this with the third cutting of lucerne, and the cattle apparently relished the straw as much as they did the hay.

EXPERIMENTS IN DRYING WHEAT.—"Taking three separate quantities of wheat ears, all of equal weight and cut the same day, the first exposed for seven days to the full influence of the sun, was found to be dry, thin and steely; the second, laid in the shade where the air would have its full effect upon it; this after laying twelve days was rather thin than otherwise, very dry but not steely—its weight was one tenth more than the first;—the third lay very near to the second in the shade, was moistened by having a little water sprinkled over it for the first six days, and then left eight days to dry; it was thin, dry, good body, very mellow, but not quite so bright as the second, although the flour was of quite as good quality, and its weight one-ninth more than the second.—*Smith on Improved Ag.*

The same writer affirms, that if wintered in comfortable warm and dry sheds, cattle will thrive better upon good straw, than those fed upon good hay, in a wet, cold and comfortless yard; that if the straw be cut and mixed with a small quantity of hay, it will all be consumed; and that by these two modes of improvement in feeding, the farmer would be enabled to winter more than twice the quantity of stock, that he can do under present existing circumstances.

OF THE ARRANGEMENT OF FARM LABOR.

The importance of order and system (says Loudon, Enc. Ag. p. 734,) has been already insisted upon, and the subject cannot be too often repeated.—To conduct an extensive farm well, is not a matter of trivial moment, or to the management of which every one is competent. Much may be effected by capital, skill and industry; but even these will not often ensure success without judicious arrangement. With it, a farm furnishes an uninterrupted succession of useful labor during all the seasons of the year; and the most is made that circumstances will admit of, by regularly employing the laboring persons and cattle, at such works as are likely to be most profitable. Under such a system it is hardly to be credited how little time is lost, either of the men or horses, in the course of a whole year. This is the great object, for each horse may be estimated at three shillings (66 cents), per day, and each man at two shillings (44 cents.) Every day, therefore, in which a man and horse are unemployed, occasions the loss of at least five shillings to the husbandman.

As the foundation of a proper arrangement, it is necessary to have a plan of the farm, or at least a list of the fields or parcels into which the land is divided, describing their productive extent, the quality of the soil, the preceding crops, the cultivation given to each, and the species and quantity of manure they have severally received. The future treatment of each field, for a succession of years, may then be resolved on with more probability of success. With the assistance of such a statement, every autumn an arrangement of the crops for the ensuing year ought to be made out; classing the fields or pieces of land, according to the purposes for which they are respectively intended. The number of acres allotted for arable land, meadow or pasture will thus be ascertained. It will not then be difficult to anticipate what number of horses and laborers will be required during the season for the fields in culture, nor the live stock that will be necessary for the pasture land. The works of summer and harvest will likewise be foreseen, and proper hands engaged in due time to perform them.

A farmer should have constantly in view a judicious rotation of crops, according to the nature and quality of his soil, and should arrange the quantity and succession of labor accordingly. Farm labor, when frosts and bad weather do not intervene, should be arranged for some months; and hand labor for some weeks, according to the season of the year.—"A general memorandum list of business to be done," may therefore be useful, that nothing may escape the memory, and that the most requisite work may be brought forward first, if suitable to the state of the weather. In this way the labor will go on regularly, and without confusion, while by a proper attention, either a distribution of labor, or an occasional consolidation of it, may be applied to every part of the farm.

The farmer ought to rise early, and see that others do so. In the winter season, breakfast should be taken by candle light, for by this means an hour is gained, which many farmers indolently lose; though six hours in a week are nearly equal to the working part of a winter day. This is a material object where a number of persons are employed. It is also particularly necessary for farmers to insist on the punctual performance of their orders.

The whole farm should be regularly inspected, and not only every field examined but every beast seen, at least once a day, either by the occupier or some intelligent servant.

In a considerable farm, it is of the utmost consequence to have servants specially appropriated for each of the most important departments of labor; for there is often a great loss of time where persons are frequently changing their employments. Besides, where the division of labor is introduced, work is executed not only more expeditiously, but also much better, in consequence of the same hands being constantly employed in one particular department.

Previously to engaging in a work, whether of ordinary practice or of intended improvement, the best consideration of which the farmer is capable, ought to be given to it, till he is satisfied that it is advisable for him to attempt it. When begun, he ought to proceed in it with much perseverance and attention, until he has given it a fair trial. It is a main object, in carrying on improvements, not to attempt too much at once; and never to begin a work without a probability of being able to finish it in due season.

By the adoption of these rules, every farmer will be master of his time, so that every thing required to be done, will be performed at the proper moment, and not be delayed till the season and opportunity have been lost. The impediments arising from bad weather, sick servants, or the occasional and necessary absence of the master, will, in that case, be of little consequence, nor embarrass the operations to be carried on; and the occupier will not be prevented from attending to the smallest concerns connected with his business, on the aggregate of which his prosperity depends.

OF DOMESTIC MANAGEMENT AND PERSONAL EXPENSES.

On domestic affairs, a hint may suffice. Young farmers beginning house-keeping, like most others in similar circumstances, are apt to sink too great a proportion of their capital in furniture, and furnishing riding horses, carriages, &c. and sometimes to live up to, and even beyond, their income. We do not mean that farmers should not live like other men of the same property, but merely that all beginners should live within their income. Even in the marketing expenses care is requisite; and the prudent farmer will do well, every penny or six-pence he lays out, to reckon up in his mind what that sum per day would come to in a year. The amount will often astonish him, and lead to economy, and, when practicable, to retrenchment. Saving, as Franklin has inculcated, is the only way of accumulating money.

In regard to house-keeping, it is observed in the *Code of Agriculture*, that the safest plan is, not to suffer it to exceed a certain sum for bought articles weekly. An annual sum should be allotted for clothing, and the personal expenses of the farmer, his wife and children, which ought not to be exceeded. The whole allotted expense should be considerably within the probable receipts, and if possible one-eighth of the income annually received, should be laid up for contingences or expended in extra improvements upon the farm.—*Enc. Ag.*

Pyramids of Butter.

Col. Meacham, of Oswego county, lately brought to this city, two pyramids of butter, the produce of his dairy, one weighing five hundred pounds, and the other nine hundred pounds. They were covered with fine white cloth, upon which were various devices and inscriptions. The Colonel had previously sent to Washington a *tub* of butter, weighing 1450 lbs! Col. Meacham's name was already favorably known to the public as the maker of the large cheeses which attracted much notice two or three years ago. But it is not the production of large cheeses, or pyramids of butter, alone, that gives to this worthy citizen a high rank for enterprise and usefulness. Col. M. is a self-educated, self-made man, and one of the best farmers in our state. His example has had a highly salutary influence upon all around him, and has tended materially to increase the products, and to enhance the value of the lands in his neighborhood, and to check, withal, the tide of emigration from thence to the far west. How highly should such a citizen be appreciated, who not only contributes largely himself by his industry and enterprise, to the public prosperity, but influences others, by his example and his counsel, to "follow in his footsteps."

Rearing of Cattle.

We would direct the attention of our farmers particularly to this branch of husbandry, as one that promises to be lucrative in more ways than one.—The scarcety of winter fodder for some years back, induced many farmers greatly to reduce their farm stock. The high prices which beef has commanded in our cities and towns, has been a further cause of the reduction of our farm stock. But there is another cause, of no inconsiderable magnitude, completely under the farmer's control, which good policy, and even humanity, imperiously require should be corrected. We allude to the practice among dairymen, of destroying their calves at two or three days old, *to save the milk* which they would require, if suffered to live. This has become an alarming, and is a growing evil, in our state, and unless it is abated, threatens the worst consequences. Thousands of calves are thus annually destroyed, we are told, in the dairy districts, from a short-sighted policy, which would sacrifice, to present gain, one of the most important branches of our husbandry. These causes, combined, have caused a comparative scarcity of neat cattle; and prices have consequently advanced fifty to one hundred per cent, until this branch of husbandry, especially since the wheat crop, from the effects of winter and the depredations of insect enemies, has become precarious,—until, we say, cattle husbandry has become the most certain, and we believe the most profitable branch of farming.

But it is not the price of cattle alone that should influence the farmer in this matter. To *keep up the fertility of the soil*, is the cardinal point in good farming. *Fertility* is the source of our profits; and the *interest* which we receive will ever be regulated by the amount of the *capital* from which it accrues.—Cattle are emphatically the cause of fertility. They manufacture the hay, the straw, the stalks, the roots, &c. of the farm into dung, and dung alone keeps up fertility. The more cattle, therefore, which are maintained upon the produce of the farm, the greater the ability to keep up its fertility—the greater the farmer's fund, and the greater the amount of produce, or of interest, which he draws from it.

We know that there are many persons who own rich new lands, who either do not believe in, or who do not practice upon, this doctrine. They say fertility is inexhaustible in their soils; and practising upon this theory, they have in a measure neglected farm stock, and directed their whole efforts to the exhausting culture of wheat. We tell them, that the first settlers in the valleys of the Hudson and Mohawk once held their doctrine, and practised upon it, till their sons have seen its fallacy, to their sorrow; and have been obliged to commence an expensive renovating process, and a more enlightened system of management, to repair the waste, and atone for the errors, of their ancestors.

Corn Stock Fodder

Is generally regarded, by northern farmers, as of secondary, or trivial importance, in the economy of feeding neat cattle; and in the usual way of harvesting, curing and feeding it, perhaps the opinion is pretty well founded. The mode of harvesting is either to top and leave the tops in the field till the corn is gathered, or to gather tops and buts, after the corn harvest. In the first mode, the tops are always laid upon the ground, exposed to all the vicissitudes of weather, for days, and perhaps for weeks. They are then bound and stooked till gathered to the barn or fodder yard, probably in Oct. or Nov. at which time those cut up after the corn is picked, are generally also brought it. Thus, after attaining to maturity, to their best condition as cattle fodder, they are exposed, for one or two months, to the scorching and deteriorating influence of the sun, winds and rain, till their nutritive properties are seriously diminished, and until a considerable portion is either spoiled or wasted. And finally, they are often pulled from the stack by the stock which have admission to them, or fed, uncut, in a dirty yard, and soon trampled under foot. Now we ask any farmer of common sense, what his hay would be worth under a like system of management? Exposed for weeks or months to the wasting influence of the weather, afterwards but badly protected, and finally fed to his cattle in a like reckless and slovenly way!—Would it not impair it half—two-thirds, of its value? Sugar, or its elements, constitute the great nutritive principle of cattle forage. This exists to a great extent in corn stalks, as is evidenced by the saccharine matter perceptible in chewing a piece of green stalk, but it is more fully demonstrated by the fact, that in our revolutionary war, molasses, for household use, was manufactured from the stalks of corn, in mills constructed for the purpose. All our hay grasses possess this nutrient property. The moment cattle forage is cut, be it grass or corn-stalks, the natural tendency is to decomposition—to separate into elementary principles—and heat, moisture and air being the agents in effecting this change—the change is accellerated in proportion as these agents are permitted to operate upon the vegetable mass. If exposed to them all, as in the meadow or corn field, the change is rapid, and the hay or straw consequently more decreased in value; but if partially or wholly protected from one or more, by being secured in stooks, cocks, stacks, or buildings, the tendency to change—to rot,—is either retarded or wholly suspended. We all know, that to expose hay for weeks, or for days, to the combined influence of these agents, is destructive to its good qualities. Precisely such, though perhaps in a diminished degree, is their influence upon corn-stalk fodder.

Let us then inquire, what mode we can adopt to secure the full advantage of this great auxiliary to the cattle yard. Fortunately the mode has already been suggested by intelligent minds, and its utility amply demonstrated in the practice of many of our best farmers. The mode of doing the thing is this:—cut at the ground the corn crop, as soon as the grain has become glazed, and while the stock is surcharged with saccharine nutricious juices; put it immediately into stooks, containing 20 to 25 hills each; secure these well with a band above the ears, and another on the bonnet, to exclude rain; as soon as the corn is gathered, which may be done in ten to fourteen days, bind and stook the stalks, and as soon as they are sufficiently cured, carry them to the barn or sheds, or secure them in stacks; and when wanted, cut them with a machine, and feed them to your cattle in a clean manger. Thus cured and thus fed, corn stalks are equal, if not superior, to hay, for the winter keep of neat cattle. In saying this, we speak from the personal experience of years—our neat cattle have been wintered,—and *well* wintered, upon them, several years; and we are happy to add, in another column of this day's Cultivator, the corroborating and unequivocal testimony of Mr. Foote, of Williamstown, in favor of the system.

There is another and important consideration we have to mention, and that is, a belief, that well cured corn-stalks constitute an excellent food, when cut, for horses. At the south, corn blades, we believe, are almost exclusively used for the winter keep of horses. During last summer, it was mentioned by a correspondent on Long-Island, that corn stalk fodder was an effectual remedy against that troublesome disease—the *heaves*. Our hack horse had for years been troubled with this disease, and it never appeared to be more oppressive to the poor animal than in October last. As soon as our stalks were gathered to the barn, we directed some to be cut and fed to him, and the practice has been kept up to this day. We will not say that this has cured him; but this we do say, that since he has been served with the corn-stalks, we have not discovered in him the least indication of the disorder.

Cultivator Premiums.

There are but three crops, two of Indian Corn and one of Ruta Baga, that have claims to the premiums offered by us in our March number; and all these, we are happy to say, are highly deserving of reward.

The estimated nett profits of these crops are $68.15, $87.71, and $134.50—products large enough, certainly, to satisfy the reasonable desires of any man, for the use, one year, of an acre of land—and probably exceeding its marketable price, in fee. The only fault we find with the accounts current of these crops, is the low estimates they make of the value of manure; and one gentleman, Mr. Osborn, has virtually considered it worth nothing, except the expense of hauling it out. These gentlemen must all be good farmers, and if so, they must know, that every load of manure, when judiciously applied to the corn or ruta baga crop, is richly worth one dollar—nay, that it adds two dollars to the value of the crop.

Of the corn crops, both are so meritorious to the cultivators, that we will not stop to inquire which is most so, but cheerfully award to each of the competitors a *first* premium.

The ruta baga crop is certainly highly meritorious, whether we regard the product or the example it holds out to others. We therefore award—

To William Ingalls, of Volney, and to Joseph F. Osborn, of Port Byron, each, a ten dollar premium, on their corn crops of 116 and 118½ bushels per acre. And

To John C. Mather, of Schaghticoke, a premium of ten dollars, on his crop of 1231 bushels of ruta baga to the acre.

The premiums will be paid in plate, on demand, in such articles as the claimants may select. And may these prizes, though small in amount, stimulate the gentlemen to whom they are awarded to persevere in the work of improvement and of usefulness, to their individual benefit, and to the manifest advantage of the public, through their excellent example.

We award the premium of five dollars, for the best plan of a barn and cattle sheds, offered in 1837, to C. N. Bement, of Albany.

On the Culture of Rape.

Our attention has been drawn to this plant by the letter of Mr. Kennedy, inserted under Correspondence; and from the experiment in its culture which he details, there is a strong probability that it may be profitably introduced among us as a farm crop.

Rape belongs to the *Brassica*, or Cabbage, genus of plants, and is cultivated extensively on the continent, and in some parts of Britain, principally for the oil afforded by its seeds. According to De Candolle and Von Thaer, the species cultivated in Germany, France and the Netherlands, is the *Brassica campestris oleifera*, while that cultivated in Britain is the *Brassica napus*. The former has hispid, or bristly leaves, is more hardy, and more productive than the latter, the product being 955 to 700 of the latter. The rape is a biennial plant, and perfectly hardy, we *now* believe, in our climate.

With a view to encourage experiments in the culture of this plant, we shall state somewhat in detail, the mode of managing the crop, its product, uses, &c.

The soil for rape should in the first place be dry—it should be rich, ploughed deep and well pulverized. Reclaimed swamps suit it well. Prepare as for turnips, or other fine seed. The seed may be sown at the same time as the common turnip, and indeed it is sometimes sown with the turnip, though the practice is a bad one—the turnips being gathered in the autumn, and the rape in July following, when the seed has attained to maturity. It may be sown broadcast or in drills. If intended to be fed off by sheep in winter, a practice recommended by Loudon, and followed in Lincolnshire, one peck of seed may be evenly sown broadcast upon an acre; but if the object is seed, or the drill culture is to be adopted, two to four quarts of seed will suffice for an acre. Resembling the turnip much in the properties of its top, it affords, in autumn and winter, a fine "bite" for sheep. It is scarcely surpassed, says Loudon, by any other vegetable, in so far as respects its nutritious properties, and that of being agreeable to the taste of the animals. The after culture of rape should be like that of the turnip, though we are afraid it would be apt to be neglected with us—that is, it ought to be kept free from weeds by the hoe, and the plants ought to be thinned to the distance of six inches.—In close crops the seed is only found on the summits of the plants; in wide ones it also covers their sides. As seed is the principal object, the thinning process should be particularly attended to. It comes to maturity in July or August.

The harvesting process is the most critical. The crop must be cut with a sickle or hook, and with care, to prevent the loss of seed, which wastes under careless management; and it should be threshed, in the field or barn without delay, and without being put into stack or mow. In moving it to the threshing floor, either a perfectly tight box to the wagon or cart is required, or a large cloth should be spread upon the bottom, and extended over the sides, so as to catch all the seeds that fall out. The harvesting should be made in good weather, and as many hands be employed as can work to profit.

The product, under favorable circumstances, is forty or fifty bushels, or more, of seed to the acre.—The seed is crushed for oil, in the same way as lint or flaxseed, and never sells for less, in England, than £30, the last of ten quarters, which is about $1.66 to $1.70 the bushel. Marshall says it may be considered as one of the most profitable crops in husbandry. There have been, says he, instances, on cold unproductive old pasture lands, in which the produce of the rape crop has been equal to the purchase value of the lands. The oil is burnt in lamps, and is used for various other purposes; but is liable to become rancid; but by being purified it is almost entirely divested of color, smell and taste, so that it will burn clear without any interruption.

Independent of the value of the seed for oil, and of the leaves as winter food for sheep, the rape crop affords other sources of profit. Rape cake constitutes a valuable material for manure. The English break it into powder, and sow it broadcast upon clover, or deposite it, at the rate of four cwt. to an acre, in drills with turnip seed. The Flemings throw it into their urine cisterns, where it dissolves, and adds materially to the fertilizing properties of the liquid. In Holland it is almost exclusively used for feeding milch cows and other farm stock; and, if we mistake not, quantities are annually exported to England, under the name of oil cake, for a like purpose. The haulm is burnt by the Flemings, and the ashes, which are alledged to be equal to potash, are employed as manure. The English condemn this practice, and say that the haulm or straw is as acceptable to cattle as hay; and the Lincolnshire corrected report adds, that when grown on fresh land, the stalk is as brittle as glass, and is superior to every other kind of food in fattening sheep.

Rape has been raised, on a limited scale, by some foreign emigrants in our neighborhood, to afford autumn feed for sheep, but never, as we can learn, for the seed. And indeed seed has been kindly sent to us for trial, but the multiplicity of our avocations have prevented our giving it a trial. A principal obstacle, at present, to its culture among us, would be the want of mills to crush the seed.

We tender our thanks to Mr. Kennedy, for calling our attention to the subject; and shall be happy to be advised of the further progress of the culture in his neighborhood.

The Calendar of Flora.

The following memoranda of the time of the flowering of the peach and apple, will show the comparative forwardness of the spring season at the different places noted, the latitudes of which are also noted. The data were collected by Prof. Bigelow, of Harvard College. The peach blossoms at all places, according to Humboldt, in the month when the mean heat is about 42° of Fahrenheit.

Places.	*N. Lat.*	*Peach.*	*Apple.*
Charleston, S. C.	32°44'	March 6 to 12.	April 4.
Richmond, Va.	37.40	Mar. 6 to Ap. 6.	April 10–18.
Lexington, Ky.	38. 6	April 6 to 15.	April 10.
Baltimore, Md.	31.21	April 9	April 14.
Philadelphia, Pa.	39.56	April 15	April 20.
New-York,	40.42	April 21–26	May 4.
Boston,	42.23	May 9	May 18.
Albany,	42.39	May 12	May 15.
Montreal, L. C.	45.35	May 12	May 25.
Brunswick Me.			May 29.

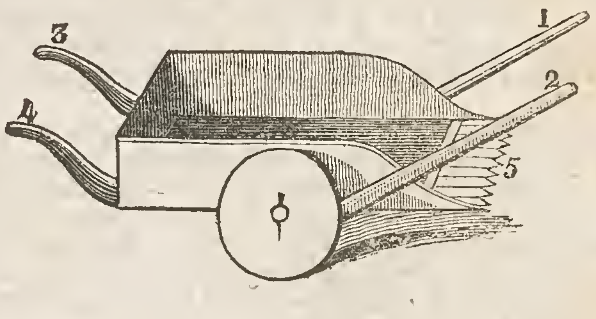
It appears from calendars of flowering in Europe, that in the average, vegetation is about a month backwarder in the United States, than in the same parallels of latitude in Europe. It appears from the above, also, that there is a difference in the forwardness of vegetation between Charleston and Albany, in a distance of nearly ten degrees of latitude, of about two months, or sixty days—averaging about six days to every degree. It is to be remarked that all the observations were made upon tide-water, except the one in Kentucky; and that every 300 feet of elevation above tide-water, in the same parallel of latitude, is equal to a degree, in the backwardness of vegetation. Thus the season at Albany would be six days earlier than at 300 feet elevation upon the neighboring Hellebergh, and 12 days earlier than at 600 feet elevation.

Clover and Clover Seed.

Clover is becoming of more and more importance, and the quantity sown is annually increasing, in proportion as the new system of husbandry progresses among us. Its tap roots penetrate and loosen the soil; its stems and foliage produce abundance of nutricious food for the neat stock of the farm; and both roots and stems, when turned over by the plough, are highly enriching to the soil. It is indispensable in alternate husbandry; and we feel justified in saying, that its liberal and judicious use, together with gypsum, upon many light soils, have added fifty, one hundred, and even two hundred per cent, to the profits of their culture. Yet there are a great many districts of our country in which its value is seemingly but little appreciated, and in which its cultivation has yet hardly been begun. There is hardly a plant grown upon the farm that returns to the soil more of the elements of fertility. There is almost a certainty, that its culture will continue to increase for some years, in a progressive ratio.

From this view of the subject it is apparent, that clover seed will continue to increase in demand, as it has continued to increase in price; and that the raising of it for market promises to be a lucrative business. The dwarf southern clover will afford a crop of hay, to be cut the last of June, and a crop of seed, to be gathered towards autumn. The price of seed is now from twelve to fifteen dollars a bushel; and suppose the acre to yield but five bushels, the profit will be enormous. Machines for cleaning the seed are already abundant, and others have been introduced for gathering the heads in the field. We give below the drawing and dimensions of one described by Mr. L'Hommedieu, in the transactions of the old Agricultural Society.

[Fig. No. 67.]



DIMENSIONS.

1. 2. The shafts, 4 feet 4 inches long, and three feet asunder.

3. 4. The handles, 3 feet long and 20 inches apart.

5. The fingers or teeth, 13 inches long.

The wheels are sixteen inches in diameter.

The machine is drawn by one horse, and guided by a man or boy. It simply consists of an open box, about 4 feet square at the bottom, and about three in height, on three sides. To the fore part, which is open, fingers are fixed, similar to those of a cradle, about thirteen inches in length, and so near as to break off the heads from the clover stocks between them, which are thrown back into the box as the horse advances. The box is fixed on an axeltree, supported by the wheels. The driver raises or lowers the fingers of the machine, so as to take off all the heads of the grass; and, as often as the box is filled with them, they are thrown out, and the horse goes on as before.

Specific Manures.

We have said, and repeated, that wheat cannot be depended on as a profitable crop, on primitive soils, without the application of animal matters and lime. The hopes of making New-England a wheat-growing country, always seem to us fallacious, from the absence, in all primitive formations, of these two essential elements, lime and animal matter. Lime is now generally admitted to be essential to a wheat soil; but as lime consists of 20 parts of the metal *calcium*, and about 7.5 of oxygen, it does not seem to furnish nitrogen. Upon this subject, we quote from the Edinburgh Quarterly Journal of Agriculture, the following, in support of our former opinions.

"On analyzing the *grain* of wheat, and the *bulb* of the turnip, (the parts for which the crops are cultivated,) it is at once found that both of them contain *elementary* principles not entering into the composition of "*common vegetable matter*," namely, *nitrogen* in the grain of the wheat, and *sulphur* in the turnip, beside which the *saline* matter is also found to be peculiar, but this last will be considered more fully hereafter. Having once, therefore, discovered that these elements are essentially necessary for the growth of the above-mentioned plants, we are evidently led to ask ourselves the question, Whence are they to be obtained? Dear bought experience has long since answered, *in animal manures.* Yes, all substances derived from the animal kingdom contain more or less of both nitrogen and sulphur, and hence the value, or, in fact, the absolute *necessity*, of such manures for the particular crops now under consideration. It may, indeed, be said by some, that 'however necessary animal manure may be for turnips, still there can be no absolute necessity for their application to the wheat crop, for, as nitrogen is the substance here wanted, surely the atmosphere will present a ready and never-failing reservoir of that element.' But it must here be remarked, in answer to such a statement, that it is exceedingly probable that the *higher* order of plants, at least, *never* obtain the nitrogen they possess from the air, but always from decomposing *animal* matter."

And what, we may be asked, are *animal manures?* Not mere vegetables, which have rotted in the yard, or passed through the cattle of the farm—not farm-yard and stable dung, in the ordinary mode of its management. The common vegetable matters consumed by the farm-stock do not contain nitrogen, this essential element of wheat. It, however, abounds in the urine of animals, and in all animal substances, as wool, hair, bone, horn, the dung of carniverous animals, or such as feed upon flesh; it exists in fish, in soap boilers' waste, impregnated with animal oil, and to some extent in shell marls.

We shall be told, probably, in contradiction to our theory, that the primitive formation of New-England has produced good wheat, and that it promises to produce it again. When first subjected to culture, even soils of primitive formation have a quantity of animal matters upon their surface, the accumulation of centuries, which may have sufficed for one or more crops of wheat; but these supplies being exhausted, the crop has failed. Art may in many cases supply the deficiency, by the application to the soil of one or more of the above enumerated animal substances; and these elementary matters may have been accumulating from ordinary manuring, until the soil has become sufficiently charged with the specific food of a wheat crop. We really fear that all attempts to raise good wheat—we mean the grain, not the straw—on soils of primitive formation, without the aid of animal manures, will be found to be rather an uphill business; and that even with this aid, it will turn out much like Franklin's whistle—will cost more than it is worth.

We will extract one other remark from the writer above quoted—which is, that "although *practice* has long ago shown the necessity of *animal* manures for the above-mentioned crops, [wheat and turnips,] still *chemical analysis* alone could ever have explained the *reason* for this necessity; thus placing the advantages to be derived from the science in a truly prominent and important light."

Properties of Wheat.

The following abstract is taken from Davy, to show, first, the difference in gluten, starch and bran, between winter and spring wheat; and, secondly, how seriously impaired the value of both is by mildew.

		Flour.	*Bran.*
Thin-skinned Sicilian wheat afforded of..	Gluten 239 Starch 722	=961	39
Middlesex wheat, (average crop,)	Gluten 190 Starch 765	=955	45
Spring wheat,........	Gluten 240 Starch 700	=940	60
Mildewed wheat of 1804	Gluten 130 Starch 520	=650	350
Do. of 1806, ...	Gluten 32 Starch 178	=210	790

Showing, in one instance, a loss of 31 per cent of flour in the mildewed, when compared with the average English wheat, and in the other of nearly 75 per cent.

It will be perceived that the spring wheat contained more gluten, the more nutritious portion of flour, than the winter wheat; and that the winter wheat from Sicily, a warm climate, contained a greater portion of gluten than that which was raised in England, a cool climate.

Education in the German States.

Some time ago, the Conductor received from the author, a pamphlet "On the establishments for public education in Bavaria, Wirtemburgh and Baden, &c. by John C. Loudon," editor of the Encyclopædia of Agriculture, &c. There are many facts embraced in the pamphlet, from which we may derive benefit, particularly from those which relate to new branches of instruction, which may properly and profitably be introduced into our common schools.

The kingdom of Wirtemburgh is represented as one of the most generally civilized in Europe. Elementary education is universally diffused. All can read and write. Schools are of course abundant. A college is established for the instruction of school teachers. The students undergo a rigid examination, and when properly qualified as teachers, they receive a certificate, which is indispensable to admit them to the head of the lowest school. Government fixes the amount of their salary, which is paid by a tax on the district.

Every child is required to be sent to school—males from 6 to 15—females from 6 to 13. An annual examination is had, at which the trustees award a certificate to those who are found to be competently instructed; and no person is allowed to be employed throughout the kingdom, who is under the age of 21, without such certificate.

In Bavaria, the system of education resembles that of Wirtemburgh. The elementary principles of agriculture, both the art and science, are taught in these schools. M. Hazzi, an enlightened patriot, has composed a Catechism of Agriculture, which the government has ordered to be introduced into all the schools. Every school has some two or three acres of land annexed to it, in which the scholars act as laborers—sowing various kinds of seeds—noticing the variety of culture, and the phenomena of vegetable physiology. A small garden is reserved for the female children to raise flowers. The elder scholars in the female academy at Carlshue study natural history, (and particularly botany,) astronomy, geography, the French and German languages, and music and drawing.

On the Winter Management of Manure

We make this preliminary remark, upon which what we have to offer is in a measure predicated, viz. that all the manure from the stables, yard and hog-pen, should be carried out in the spring, for the corn and potato crops.

The objects to be obtained in the winter management of manure, are,

1. To prevent waste by leeching and drainage;
2. To prevent its becoming fire-fanged; and,
3. To prevent more than moderate, or incipient, fermentation.

1. Where cattle yards are upon a slope, or are convex, or nearly upon a level surface, the liquid portions of the manure, which may be termed in a measure the cooked food of plants, continually pass off, and are lost. Heavy rains, and the drip from the barns and sheds, also, passing through the manure, in its escape from the yard, leech, and deprive it of its finest and most fertilizing properties.

The remedies against this evil, consist, *first*, in giving a concave, or dishing shape to the yard. The earth excavated from the centre being deposited upon the borders, which should be fifteen or twenty feet broad, with a slight inclination to the centre, a dry passage to the barn is secured, and a sufficient space of dry ground to feed the stock upon which run at large. *Secondly*, the yard should be bedded, after it is cleaned, with peat or swamp earth, if the farm affords it, six to twelve inches deep; or if this is not to be had, with any other porous waste earth—and afterwards should be kept well littered with straw, stalks, potato tops, and the coarse grass and weeds of the farm. The shape of the yard prevents the escape of the liquids, and the earth and litter absorb and become enriched by them. Even should the liquids of the yard be dried up, as they are in summer, the earth and litter will retain the fertilizing matters which they held in solution. By these operations alone, the quantity of manure will be double what it is where they are neglected. *Thirdly*, in endeavouring to prevent an excess of water in the yard, by catching in gutters, and conducting off, what falls from the buildings. And *fourthly*, by constructing a reservoir, under ground, for the reception of the liquids that unavoidably flow from the yard, and particularly for the urine from the stables. In this latter mode, a great accession may be made to the fertilizing resources of a farm, and a material ohtained, fitted for the immediate wants of a growing crop.

2. When dung is accumulated in large masses, either when thrown from the stables, or in the fields where it is to be applied, even if protected from the weather, a violent fermentation takes place, moisture is exhausted from the mass, and the dung becomes what is termed *fire-fanged*—dry, light and mouldy, and seriously impaired in its value.

To avoid this, in the yard, spread the manure from the stable, occasionally, over the yard. It thereby becomes blended with other matters less disposed to ferment, is trodden by the stock, and the air, one of the agents in causing it to ferment, is in a measure excluded. Under cover, it should not be suffered to accumulate in excess, without the admixture of earthy matters, which would retard fermentation and preserve moisture. It is often convenient to draw manure to the field in the autumn, or winter, where it is to be used. If such manure has not undergone fermentation, it should never be laid in heaps of more than three feet in depth, or six or eight loads together, the surface should be handsomely smoothed off, and then covered, when the frost will permit, with six or eight inches of sod or earth. This prevents violent fermentation, and the loss of the gaseous matters which fermentation always sends off.

With the foregoing precautions, there is little danger of fermentation proceeding to a wasteful or improper length before the manure is wanted for the corn or potato crop.

What farmer is there, who makes any pretentions to economy, who would not feel insulted to be told, that he carelessly wasted one half of his family food, or of his cattle food—one half of what his farm produced for animal subsistence? Where is the matter of difference, whether he wastes the food of his family, of his animals, or of his crops? His crops feed both his family and his live stock; and unless he feeds his crops, the others must ultimately suffer the penalty—for the earth, though a kind and prolific mother, cannot always give, when we withhold from her the means of giving. Return to her *what is no longer of use to us*, and she will requite us with her richest blessings. Let us bear in mind, that every animal and vegetable substance, which we return to her bosom, she will faithfully elaborate into new organized matter, for our pleasure and profit; but that if, like the prodigal, we exhaust the parental treasure, it can no longer supply us with bread or meat. Too many who occupy a rich virgin soil, may be likened to useless drones who waste their patrimonial wealth: they waste that which would benefit both themselves and their children.

The Oak the Emblem of our Country.

Our country may be likened to the oak—the three great business classes to the roots, branches and leaves, and the strong tough trunk, to society in mass. Agriculture may be compared to the roots, which provide food and the elements of wealth; manufactures to the leaves, which elaborate, and convert to useful purposes, the materials furnished by the roots—and commerce, to the hranches, or channel of intercourse between the roots and the leaves. Without the branches, the roots and leaves are deprived of their reciprocal aids. Without the leaves, growth must cease. Without the roots, leaves, branches and trunk must perish. The root can send forth a new stem, branches and leaves; but neither the stem nor branches, nor leaves can, ordinarily, either separately or conjunctively, produce new roots. All are, primarily, nourished from the soil, and all being in healthful condition, form a whole, which can, like the oak, buffit the storm, be it the local thunder gust, or the more formidable foreign north easter. Let us, therefore, cherish and protect all—and let us specially nurture the root, as the primary source of life, growth and usefulness, to the stem, branches and leaves. To carry out the comparison, we will liken the acorns to the "loaves and fishes" of office, and the moss, which feeds upon the oak, to the parasytic drones who live upon society. N. B. In our comparison of the farmers to the radi*cles* of the oak, we beg not to be misunderstood—they are not radi*cals politically*, but the radi*cles positively*.

Resources of Fertility in the South.

Throughout the entire oceanic deposite, from Connecticut to the Capes of Florida, or what may be called the flat sandy districts on the Atlantic border, new elements of fertility are daily being brought to light, and this will undoubtedly continue to be the case for years, as science is made more and more subservient to the purposes of husbandry. So that it would seem, that Providence has every where scattered the means, if man will but properly use them, of rendering the soil prolific, in all that is essential to the wants and comforts of the human family. The green sands of New-Jersey, Maryland and Virginia, abounding in potash, have already done wonders in imparting fertility to soils that were deemed barren and unworthy of culture; the shell marls, and immense banks of marine shells, which seem to increase in magnitude as we go south, are coming into useful action, chiefly through the instrumentality of E. Ruffin, whose excellent treatise upon calcarious manures ought to be in the hands of every farmer; and we see recently announced the discovery, by Dr. Cooper, of immense beds of calcarious matters, of uncommon richness, in the pine or sandy districts of South Carolina—a material exactly adapted to the wants of those districts. We have in our own state immense beds of marl, fitted to impart fertility to our soils, yet but imperfectly known, and less properly appreciated in value.

National Silk Convention.

A convention of 170 gentlemen, engaged in the silk and mulberry business, met at Baltimore on the 12th Dec. and held a session of three days, and formed the "American Silk Society." It was resolved in these meetings, to establish a national Silk Journal; to recommend the organization of state societies, auxiliary to the national society; to offer premiums to encourage the culture and manufacture of silk; to recommend the Piedmont silk reel; to recommend to the cultivators of the mulberry, *to turn their attention to the production of silk*; to solicit the states to pass laws to encourage the silk culture, and to protect plantations of the mulberry; and that another national Silk Convention be held at Washington, on the second Wednesday after the first Monday in Dec. next.

The Grain Worm,

Which is complained of in the west, and which has been particularly spoken of in the Genesee Farmer, we are induced to believe, is not identical with the insect which has for years devastated our fields. Will the editor of that Journal, or some other individual, describe the grain-worm of the west?

Boynton's Straw-Cutter.—This recently patented machine, of which a figure, &c. is given in our advertising sheet, is highly spoken of; but we are unable to speak personally of its merits, not having seen it in operation, or even seen the machine.

Root Culture.

Persuaded that root culture is ultimately to effect a great improvement in our husbandry, we propose to make it the subject of some remarks in this and subsequent numbers. The advantages which root crops offer to the farmer, are the following, viz.—they furnish the most food for animals, and the most food for vegetables in the form of dung; they are least exhausting to the soil, which they serve to divide and pulverize; they are excellent to alternate with grass and grain in convertible husbandry; and for these reasons they are the most profitable to the cultivator, on all farms which will admit of their culture. We intend to direct the attention of the reader to the different roots which are adapted to our field culture, to the best modes of managing the crops, the manner of preserving and feeding them properly, the expense of culture, the average product, and, so far as our data will justify, state their relative value as cattle food.

The roots we intend to notice are, the Potato, the Turnip, the Beet, the Carrot and the Parsnip. But before we proceed to consider them individually, we will offer some

PRELIMINARY REMARKS.

Five things are essential in the culture of the roots we have named: 1st. A dry soil; 2d. A rich soil; 3d. A deep worked soil; 4th. A well pulverized soil; and 5th. Good after culture. The crop will be abundant in proportion as these several requisites are present, and defective in proportion as they fail.

By a *dry* soil, we mean a soil that is not *wet.*—*Moisture* is beneficial to all crops, but *water* is detrimental to all root crops, though it repose upon the subsoil, or but occasionally saturate the surface.—Hence where roots are grown upon soils that are tenacious and flat, or upon those which repose upon an impervious subsoil, the land should be thrown into ridges, and the furrows kept open for the free passage of the water in heavy rains.

A rich soil is as essential to good crops as rich and abundant food is to the fattening of farm stock. We all know that short pasture and coarse fodder will *keep* cattle, though it will not *fatten* them. So with roots—they will *live* and *grow* upon a poor soil, but their product and profit will be great only on a *rich* one. The advantage to the crop, as well as the animal, will be in proportion to the quantity of dead organic matter which it converts into living organic matter—into vegetables and into meat. Ordinarily speaking, a good dressing of manure will double the products of a root crop. To illustrate this fact more fully, we abstract the following tabular statement from Arthur Young's experiments in planting potatoes. The preparation and culture were alike in all. The numbers to which the asterisk (*) is affixed were manured crops.

No.	Preceding crops.	Expense. £ s. d.	Product, bushels.	Profit. £ s. d.	Loss s. d.
1	Fallow, ...	3 19 1	104 at 1s.6d	2 18 5	0 0
2	Barley, ...	4 5 9	128 2 0	3 11 10	0 0
3	Wheat, ...	6 13 6	46 0 20	0 0 0	0 0
4*	Do	7 16 10	101 0 20	2 5 6	0 0
5	Do	6 2 6	39 0 20	0 7 6	0 0

The three manured crops, it will be seen, gave an aggregate product of 472 bushels, and an aggregate nett profit of £22.10.3, ($99.90, say $100;) the three adjoining plats, treated like the others in all respects but manuring, gave an aggregate nett product of but 132 bushels, and an aggregate nett profit of but 8s. 11d. ($1.96, say $2;) thus showing that the manure, in these cases, caused an absolute gain of $98, and that where it was not used, there was in fact only a nominal profit of *two dollars!* These facts will serve to show the reader, *first*, the great value of manure in farming operations, and to stimulate him to save and economise it; and, *secondly*, to show him the propriety of *always* manuring his potato crop, for which it is universally admitted the unfermented dung and litter of his cattle yard is *best* fitted.

A deep worked soil is necessary, that the tap roots of the beet, carrot and parsnip may not only penetrate freely, and enlarge their length and volume, but that their radicles, which are principally upon their lower extremities, may there find food for the plant. The fibrous roots of the potato and the turnip are equally benefitted by a deep tilth, from which they can draw nourishment, and find shelter from drought.

The pulverization of the soil is essential to the germination of the seed, to the easy extension of the roots, and to the free circulation of air and moisture, and the admission of solar heat, all necessary to prepare and transmit the food to the growing plants.

Thinning the plants and keeping them free from weeds, and the surface of the soil open to atmospheric influence, is of great importance. If the soil is dry, and rich, and deep, and well pulverized, the labors of the husbandman will yet not avail much, in root crops, if he suffers his plants to be injudiciously crowded, or to be choked and robbed of their food by rank growing weeds. And as prevention is better than cure, the thinning and cleaning processes should be commenced early, and rigidly persevered in, not only that the weeds may not exhaust the fertility of the soil, but that the latter growth may not mature their seeds, and thus perpetuate the evil.

In our next number, we shall treat of the culture, &c. of the root crops named in the commencement of this article.

Beet Sugar.

We notice by a letter from the Hon. H. Ellsworth to the editor of the New-York Observer, that important improvements have been recently made in France, and the neighboring countries, in the process of making sugar from the beet root. "The difficult and tedious process of ordinary evaporation, with all the concomitants of blood, animal carbon, &c. &c. are to be dispensed with, and instead of three, four and five per cent, *nine* per cent is surely to be obtained, in less time, and with half the expense: in addition to this, the common sugar is *refined* without any new solution, or even changing the moulds." "Experiments made before the French academy, show that there are in 100 lbs. of beet, 85 lbs. of water, 10 5-10ths pounds of sugar, 5-10ths of mucilage, and 4lbs. of fibrous matter. This was extracted by M. Becaud in eight minutes, by the aid of heat and pressure."—The beets are now sliced, dried, reduced to powder, and packed, and in this case will keep a long time. When used, a little water is put to the powder, which abstracts the saccharine matter, the liquid is evaporated, and crystilization formed. The sugar is now said to be made at an expense of five cents the pound, including the cost of the beets, and excellent refined sugar costs about seven cents. With such results, the production of this article among us, on a large scale, is rendered almost certain.

The Farmers' Garden.

ORNAMENTAL DEPARTMENT.

Start not at the caption, brother farm-rs. You all have your hobbies, which administer to your pleasure, without adding substantially to your purse, or your enjoyments. Flowers are the hobbies of the ladies, and of men, too, of refined taste. Flowers are the handy-work of the Creator, intended to gratify, not the animal appetite, which we possess in common with the brute, but the more refined sensations which belong exclusively to man. Their inimitable and diversified pencilings--their unsurpassed fragrance and beauty—are calculated to excite our admiration and to awaken our best feelings. "Behold the lilies of the valley; they toil not, neither do they spin; and yet Solomon in all his glory was not arrayed like one of them." We seldom if ever saw in the master or mistress of a choice flower garden, a person of bad passions or of bad habits. Accustom youth, therefore, to cultivate and to admire the flower garden, as a rational means of making them agreeable to others and happy in themselves.

The ornamental department of a garden consists of dwarf trees, shrubs, including woody creepers, perennials, biennials and annuals. These may be cultivated exclusively in a flower garden, they may be interspersed in a fruit or kitchen garden, and the trees, shrubs and perennials are peculiarly appropriate for court-yards and grounds about the dwelling. Our notice of them will necessarily be brief. We shall class them under the appellations of trees, shrubs, perennials, biennials and annuals.

DWARF TREES,

Suitable for a court-yard, or for planting about dwellings, are the mountain ash, European and American, the magnelias, the glauca and acuminata being hardy, and the macrophylla and tripetela being considerably so—the Siberian crab, of which there are several varieties—the double flowering cherry and peach, the double white and scarlet flowering hawthorn, &c. Evergreens may be intermixed, about the dwelling, more or less, according to the extent of the grounds, as may also fruit and forest trees. Of the former, the white pine, fir, arbor vitæ, spruce, Swedish juniper and red cedar, are all ornamental, and add to the diversity and beauty of rural scenery.

SHRUBS.

1. Althæa *Frutex.*—This is a handsome shrub, which flowers in August and September, rather tender for this latitude, but sufficiently hardy as far north as 42°. There are several sorts, having different coloured flowers, double and single; the single flowering are the hardiest. It may be propagated by seeds or suckers. Gather the seeds in autumn, and sow the spring following.

2. Almond, double flowering—*Amygdalis nana*—of dwarf growth, and one of the earliest and most beautiful flowering shrubs. It produces wreaths of flowers resembling small roses. Propagates rapidly from suckers.

3. Azalea, *wild honeysuckle.*—There are several indigenous kinds in our woods, all ornamental, and the white peculiarly fragrant.

4. Box, *buxus*—though not a flowering plant, is highly ornamental for edgings. It is a dwarf evergreen, propagated by cuttings and by dividing the roots. Requires some protection in northern winters.

5. Brier, sweet, *rosa rubiginosa.*—Though abounding in our fields, this is a pretty plant in the shrubbery, both on account of its fragrance and of its foliage and flowers. It is too common, like many other native plants, to be duly appreciated.

6. Bignonia *radicans*—Trumpet flower—a splendid climbing shrub. One variety, the *flammea*, has yellow flowers; another, *coccinea*, bright scarlet flowers. Propagated by suckers. Rather tender here, but requires no protection fifty miles south.

7. Cassia *Marylandica.*—Has pretty foliage, and produces many small yellow flowers. Propagated by seeds. Though the top is sometimes injured by the winter, it springs again from the root, and flowers the same season.

8. Clethera *alnifolia.*—A very common shrub, which produces fragrant flowers in clusters in autumn.

9. Cranberry, high—*Viburnum oxycoccus*—a shrub abounding in swamps and wet grounds. It wants nothing but a foreign origin to make it a desirable plant for the shrubbery.

10. Corchorus *Japonica*—Japan globe flower—will stand the winter in a protected situation, though it will not flower so well as when placed in a green-house. Flowers of a golden yellow, double, and much admired. Stem and foliage handsome. Propagated by suckers.

11. Fringe Tree—*Chionanthus Virginica.*—A beautiful American shrub, covered with white flowers in June. Hardy. Propagated by layers.

12. Fringe Tree, Venetian Sumac—*Rhus cotinus*—a singular shrub, loaded during summer with tufts of russet coloured down. Propagated by layers and suckers.

13. Glycine, *frutescens*—a perennial climber, with variegated flowers, much admired. A Chinese species *G.* (*sinensis*,) is less hardy, though not less beautiful.

14. Honeysuckle, *Caprifolium.*—This is a family of beautiful climbing shrubs. The scarlet and yellow monthly, the oak-leaved and the woodbine are hardy. Other species are less so. They are beautiful for arbors and walls.

15. Kalmia *latifolia*, commonly called Laurel, a beautiful evergreen flowering shrub of our mountains and forests, south of Catskill and Northampton. Like all other evergreens, it should be transplanted in the season of its growth—May, June and September being the best months to remove them, taking care to counteract evaporation, by spreading coarse litter over the roots when transplanted.

16. Lilac, *Syringa.*—Handsome flowering shrubs, of which we have the white, purple, Siberian, Persian and Chinese, the latter too tender for northern winters. They all readily propagate by suckers.

17. Lonicera.—A family of upright shrubby plants related to the honeysuckle, and perfectly hardy. The Tartarian and Siberian (or rather Iberian,) are beautiful flowering shrubs, easily increased by layers or cuttings.

18. Mezereum, *Daphne mezereum.*—A dwarf shrub and hardy, which is covered with pink flowers in March or April, before the leaves expand. Two feet high. Propagated by seeds.

19. Pæonia, *moutan*, or Chinese tree pæony. A diminutive shrub, but affording the most brilliant flowers. There are three varieties, the common, poppy-flowered and the rose coloured. They are of recent introduction, and have been generally cultivated in the green-house, but are found to be perfectly hardy in the open ground. Propagated by offsets.

20. Pyrus *Japonica*—Japan quince.—A thorny hardy shrub, covered with brilliant scarlet flowers in the spring, and also often flowering in autumn.—There is also a variety producing white flowers. This plant would make a strong and an ornamental hedge. Propagated, like horse-radish, by cuttings of the root.

21. Pyracantha, or evergreen thorn, is a pretty ornament in the shrubbery. Rather tender.

22. Rhododendron, *maximum*—rose bay.—A native evergreen of our state, of rich foliage, and clusters of beautiful flowers.

23. Rose acacia, *Robina hispida*—a hardy shrub that propagates rapidly, and produces handsome flowers

24. Rose, *Rosa.*—Of this favorite plant, botanists

enumerate some sixty species. The varieties are almost without number, and are annually multiplied by nature and art. The principal species for garden culture are, 1, the *spinosissima*, or Scotch rose, admired for its foliage as well as flowers; 2, the *Damascena*, or damask rose, embracing many termed perpetual roses, that is, blooming till checked by the frosts of autumn; 3, *centifolia*, Provens or hundred leaved, including the mossy varieties; 4. the *gallica*, or officinal, embracing the largest number of cultivated varieties; 5, *alba*, or white; 6, *rubiginosa*, or sweet brier; 7, *Indica*, or Chinese, including Bengal; and 8, *semperflorens*, or ever-blooming. The *moschata*, *Lawrenceana* and *Banksiæ*, are also cultivated, particularly in the green-house. The flowers of the rose are of all colours, from a pure white to a bright yellow and very dark red—some are dwarfs, some tall growers, and some climbers. A dozen plants, embracing different colours and varieties, are a great ornament in a court-yard or garden. Most of the varieties of the rose propagate by suckers, others require to be layered, and some are propagated by cuttings. Suckers may be planted in the autumn or spring, and should be cut down to five or six inches; and the ground should be kept clean and in good order. All the weak, dead or dying wood of roses should be carfully taken out, and it is the practice with many to cut them down in spring, to a certain height, say one or two feet, except climbing varieties, to produce strong flowers.

25. SNOWBERRY, *Symphorea racemosa*—is a small shrub, which produces clusters of white fruit in autumn, and is ornamental. Propagates freely by suckers. *S. Punica*, or crimson berried, which carries its berries in winter, is also ornamental.

26. SPICE-BUSH, *Laurus benzoin*—a native of our woods, is a desirable inmate of the shrubbery.

27. SPIRÆA.—Several species, with delicate flowers, which are indigenous, are worthy of culture.

28. STRAWBERRY TREE, *Euonymus*—white and red fruited, are highly ornamental, and are readily propagated from the seed.

29. SYRINGA, *Philadelphus*.—There are three species, all worth cultivating, admired for their flowers, and the *coronarius* (mock-orange,) for its fragrance. Propagated by suckers.

30. SWEET-SCENTED SHRUB, *Calycanthus floridus*—has flowers of a brown purple colour, of an agreeable odour, like spices—leaves fragrant.

Perennials, biennials and annuals in our next.

Blight in Grain caused by Barberry Bushes.

We find a strong confirmation of the correctness of Sir Joseph Banks, in saying that barberry bushes caused rust or mildew in corn crops, in a communication of the Rev. Dr. Singer to the Highland Society of Scotland. The Doctor states, that the loss annually sustained in Dumfriesshire, by this distemper on the crops, amounted to more than £1000, or 4,444 dollars; that Sir W. J. Hope, to test the correctness of Sir Joseph's theory, caused the total extirpation of the barberry bushes upon his estate; and that *since that was done, and for above twenty years, no such distemper has appeared in his fields.* And he adds, the same thing has been done in some parts of Ayreshire, and the same result has followed.

It is not intended to be understood, that the barberry bush is *the* cause, but merely *a* cause, of the mildew. The mildew, or rust, is known to be a parasite; but it is contended, that this parasite belongs to a genus of plants; that different species infest, exclusively, different plants, and that that upon the barberry bush is not the species found upon wheat, oats, &c. The mildew prevails where there are no barberry bushes; but if we admit the malign influence of this bush upon grain, we may with equal propriety admit, that other trees and shrubs which, like the barberry, are the home of rust, as the poplar, willow, and a great many others, have an equally malign influence upon the grain. Two contingencies must occur, it would seem, to favor the propagation of mildew—plants affording its seeds, and a suitable state of the atmosphere to waft these seeds to the standing grain.

Recipes for the Family.

Cement to mend broken china or glass.—Garlick stamped in a stone mortar; the juice whereof, when applied to the pieces to be joined together, is the finest and strongest cement for that purpose, and will leave little or no mark if done with care.—*Dom. Ency.*

Cement for stopping cracks in cast iron boilers.—Common salt by measure four parts, smithy slack one part, flower of sulphur three parts, flour one part, water to make the ingredients into a paste.—*Ib.*

Another which we have proved.—Beat up the whites of eggs, and add powdered unslaked lime to make a paste, and fill with it the cracks in iron vessels.—Though it does not reunite the iron, it will prevent the vessel leaking.

A cement that resists the action of fire and water.—Take half a pint of milk, and mix it with an equal quantity of vinegar, so as to coagulate the milk. Separate the curd from the whey, and mix the latter with the whites of four or five eggs, after beating them well up. The mixture of these two substances being complete, add quick-lime to them which has passed through a sieve, and make the whole into a thick paste of the consistency of putty. If this mixture is carefully applied to broken bodies or to fissures of any kind, and dried properly, it resists fire and water.—*Ib.* [We have tried it successfully to stop leaks around chimneys in the roof.]

Cement for a floor.—A very hard and dry, and also incombustible cement for floors, in lieu of boards or bricks, is, tar thickened with pitch, and while hot made into a plaster with common wood ashes, as much as the hot liquid will take up.—*T. Cooper.*

For Shoe Blacking.—Mix lampblack with a little sugar and the white of an egg: Then dilute with stale beer.—*T. Cooper.*

In grafting, Wilson, in the economy of the kitchen garden, recommends fresh cow-dung, instead of clay or composition, for covering the wound—merely tieing over it a piece of bladder or oil cloth to prevent its being washed off by the rains. From the known healing qualities of cow-dung, we have little doubt but it would prove an excellent substitute.

To make salt butter fresh.—Put four pounds of salt butter into a churn with four quarts of new milk, and a small portion of anatto; churn them together, and in about an hour take out the butter, and treat it exactly as fresh butter, by washing it in water, and adding the customary quantity of salt. This is a singular experiment. The butter gains about three ounces in each pound, and is, in every particular, equal to fresh butter.—*Dom. Ency.*

To purify Tallow.—When the tallow you are about to employ to make candles, is very dirty or rancid, an ounce of pearlash to about ten pounds of tallow, put into the water where the tallow is melted, is of service.—*Cooper.*

A cheap mode of preserving Plums and Grapes, has been communicated to us by a female correspondent. The process consists in alternating them in an earthen pot, the bottom of which should be previously covered with melted butter, with sugar—every three thicknesses of fruit to receive a slight sprinkling of sugar. The pot when filled, is to be covered, and set into an oven gently heated, so that the fruit will crack open, and kept there until the juice becomes thick or candied. The fruits may then be taken out, packed close in stone jars, covered with a little sugar, and kept for use, and will retain their natural flavor. When used they may be sweetened to suit the taste, and if wanted for pies or puddings, a little warm water put upon them will cause them to swell and become tender. The benefit consists more, we suspect, in retaining the natural flavor of fruit, than in the economy of sugar.

A Yankee desideratum—Pumpkin Pie, good Pumpkin Pie, without molasses or eggs! Accompanying the above, we have an assurance, that a new Shaker pumpkin, a cross of two choice varieties, is so rich and fine grained, that it requires neither sugar nor eggs to convert it into first rate pumpkin pie. Nor is this all, the pumpkin does not require to be divested of its rind, but merely scraped, ere it is boiled.

Remedy against Moth.—Our furs, and our woollen apparel, &c. are liable to be seriously injured by moth, in the summer season, when they are not in use.—We give the following simple preventive, which, although known and practised by many, may be new and servicable to some. Put your furs and wollen apparel into linen or hempen bags, and sprinkle the bags with spirits of turpentine—moth will not touch them.

A Butt Hinge Manufactory,

Is now in operation at West-Troy, the first we believe in the United States, and on an improved principle. With half a dozen boys and a couple of men, it will turn off a hundred dozen pair of door butts in a day, of a quality superior to those ordinarily imported, and at as low a price.

The best Manure for Clay Soils,

Is sand and ashes, or sand and lime: also plough deep, and expose it in the autumn in ridges, throughout the frost of winter, as the brick-makers are accustomed to do.—*T. Cooper.*

Stone Walls in Ireland,

Are built, says the Roscommon Report, without mortar, by dry wall masons, with nearly the closeness and accuracy of house walls. They build by a frame, nearly two and a half feet at the bottom, and eighteen inches at top. These are the dimensions suitable to a permanent wall six feet in height, which is usually coped by two substantial sods of three inches in thickness. The first is laid with its grassy side down, on about an inch of level mould, on the top of the wall; and the second inverted upon that, with the grass uppermost. This species of fence, with very little attention paid to it, will be safe at the end of fifty years. The expense of such a wall in Ireland, including quarrying and drawing the stone, is but 5s. 7d.—about $1.20—per running perch. In proportion to the diminution of height—and five feet would be deemed high enough with us—will be that of width and expense of building.

A table of various Foreign Coins, &c. with their value in Federal Money, as established by an act of Congress.

	$	d.	c.	m.
Pound sterling,	4	4	4	0
Pound of Ireland,	4	1	0	0

Economy of Health.

We had forgotten our promise to give occasional extracts from this admirable work of Dr. Johnson, till reminded of it by a friend. We now proceed to make some extracts from the seventh septenniad—from forty-two to forty-nine years.

"SEVEN TIMES SEVEN! Awful multiple!—This is the crisis of human existence; for, however we may conceal it from others, or even from ourselves, the decline of life commences with the seventh septenniad. At that period the tide of existence has swelled to its utmost volume, and its last and highest wave has left its mark on the craggy rock and golden sands. It is true that, while contemplating the ocean, for some time after the ebb-tide has commenced, we do not remark the subsidence of the waters—unless we watch the shores from which they recede. Then we will perceive indubitable proof of the turn of the tide. So it is with human life. For some time after the meridian of manhood, we recognize not the decadence of the stream—until we reluctantly and sorrowfully remark certain changes for the worse in our corporeal—perhaps also in our mental powers! There are, even in this early period of declension from the meridian, certain admonitory phenomena that cannot be wholly overlooked by the most thoughtless individual. A grey hair will obtrude its unwelcome presence, and, if plucked out, will return soon, with half a dozen companions! Pleasures of all kinds, but especially of a material nature, begin to lose something of their exquisite relish, and are succeeded by something more than mere satiety. Bodily exertions begin to be, not only curtailed in their range or amount, but the period of recruit becomes proportionally extended. Impressions on mind and body are less vivid. Our wine excites us less; and even the delights of convevialiaty and intellectual intercourse experience a diminution of intensity!

"It is in the seventh septenniad, too, that the three master passions of the soul, love, ambition and avarice, come nearer to an equipoise than at any other epoch. These passions are never, indeed, exactly equipotent. One is always more powerful than either of the other two—sometimes stronger than both together. Thus, in youth, love predominates—in manhood, ambition—in age, avarice. Still it is in the seventh septenniad that the antagonism of the three passions come nearest to an equilibrium. Ambition has, generally, the mastery. Love has lost much of his influence—and avarice, under various masks, as domestic economy, desire for providing for a young family, &c. &c. begins to pull against the other passions, with augmenting force and confidence. Having once gained strength, this passion never quits the field till it overcomes, and finally extinguishes one or both of its antagonists.

"It is towards the close of this septenniad, also, that the GRAND CLIMACTERIC of woman takes place. Forty-nine is an important epoch in female life—an eventful crisis, which often turns the balance between weal and wo—between steady health and dangerous disease!—If woman passes this period unscathed, she stands a good chance of a serene and quiet descent along the slope of existence in the vale of years, where the last debt to nature is to be paid! But it behoves her to be on her guard during the whole of the seventh septenniad, and not to allow fashionable dissipation, late hours, and gossamer dress, to render her grand climacteric the crisis of her fate."

Our author next proceeds to speak of what he denominates the "Patho-protean malady," as occurring in this septenniad, and as a *master-malady* of recent origin. "No name, no description of it," he remarks, "is found in the records of antiquity, or even of the middle ages. It is clearly the offspring of civilization and refinement—of sedentary habits and intellectual culture—of physical deterioration and mental pertrubation—of excitement and exhaustion." * * * "Though millions have felt it, no one can describe it—though thousands have studied it, no one has been able to frame for it an accurate definition. And no wonder. It is a PROTEUS which assumes the form, and usurps the attributes of almost every malady, mental and corporeal, that has scourged the human race since the creation of the world."

* * *

"There are numerous causes of this modern scourge, which cannot well be classed under the heads of either the MORALE or the PHYSIQUE. They partake of both. Such, for instance, are the habits and pursuits of a people. In this country commerce and manufactures preponderate over agriculture and pasturage—and therefore sedentary predominate over active habits. The factory and the counting house are not only more unhealthy, in a *physical* point of view, than the hills and the vales, but they are much more detrimental to the *moral* constitution of man. The labor is thrown on the head and the hand—and that in bad air—rather than on the body and legs, under the canopy of heaven. This difference contributes largely to the support of the PROTEAN malady, especially when aided by the competition of trade, the animosity of politics, and the rancor of religious bigotry. These and various other moral and physical agents have, unfortunately, increased since the termination of a long and sanguinary conflict with the common enemy, during which internal dissentions were swallowed up in national enthusiasm, and redundancy of population was kept in check by the waste of war! Peace, therefore, with all its blessings and comforts, is not without its alloy. Our gigantic struggles with foreign foes are now transmitted into fierce contentions between opposing factions. Every evil passion is enlisted in this domestic strife.—The forum, the bench, the hustings—nay even the pulpit—pour forth, like volcanoes, the destructive elements of discord, hatred and animosity, among all ranks and classes of society."

"The pith of nearly all that has been written on HYGIENE, or the prevention of diseases—and of the protean disorder among the rest, might be included under two heads—almost in two words—TEMPERANCE and EXERCISE. But temperance means much more than mere moderation in eating and drinking. It comprehends moderation in all our pleasures and enjoyments, mental and corporeal—it prescribes restraint on our passions—limitation of our desires—but, above all, limitation of our ambition.

"Our physical wants, like the trade winds, vary not materially, in direction or force; not so the passions.—They are the tempests of life, which too often set at defiance the sails and the rudder, driving the vessel upon shoals and quicksands, and ultimately wrecking her altogether!"

* * * "But it would be wrong to pass over the various miseries rusulting from the "PLEASURES OF THE TABLE." The intellectual and sensual banquet has too many charms for soul and body, not to lead into almost daily excess, every class of society, from the savage to the sage! Even here the immaterial tenant seduces its material tenement into woful sufferings. We hear a great deal, indeed, of "the feast of reason and the flow of soul:" but, for my own part, I have too often observed this intellectual festival to take place where

'Malignant CHEMIA scowls,
And mingles passion with the nectar'd bowls.'

It is more curious than consolatory to scrutinize, with philosophic eye, the workings of turtle, champaign and conviviality on those fierce faculties with which metaphysicians have invested the immortal principles of MAN. Without diving into these mysterious and dangerous investigations, I shall only remark, that *every* faculty of the mind, as well as every function of the body, comes under the influence of the above mentioned material agents, and in a manner that is well worthy of investigation, in regard to the immediate subjects of this essay—HEALTH and HAPPINESS.

"In the '*Feast of Reason*,' as it is called, which is generally accompanied by food of a grosser kind, we find the energies of the mind called forth—one would almost say *created*—where they were previously dormant. Sallies of wit and humor—sentiments of noble philanthropy, exalted morality, and even fervent religion, spring forth at the festive board, which lay in abeyance till that hour! It is then that friendship opens our heart,—the miser his purse,—bigotry widens the circle of its charity—the debtor forgets his creditor—the creditor forgives his debtor—the slave breathes the air of freedom—penury becomes possessed of temporary or, at least, ideal wealth—and stranger still, riches are invested with momentary happiness!

"Are these remarkable phenomena of the *mind*, unconnected with, or independent of, any corresponding phenomena in our physical organization? Far from it! Savory viands and generous wines stimulate the material organs, accellerate the circulation, and call forth the mere *animal* spirits, before they elicit the *intellectual* corruscations. And as excitement of the body produces excitement of the mind, so passions of the mind kindle up excitation in the corporeal fabric. On the stage and at the bar, passion is more frequently feigned than felt; but in the pulpit and the senate, religious fervor and political disputation will call forth the most violent agitation of the body through the medium of the mind. Painting, poetry, music and oratory, cannot raise emotions in the mind, till they have first excited certain nerves of *sense*, and, through them, the very brain itself—the organ or instrument of the mind. This is the grand consideration, as far as health and happiness are concerned. It establishes this important axiom,—little understood or attended to by mankind at large—namely, that whenever the stream of life, whether moral or physical, mental or corporeal, is accellerated in its course beyond the nominal or medium current, it must experience a corresponding retardation in turn—and these inequalities in the speed of the stream must inevitably damage, sooner or later, the banks between which it is enclosed. There is not an axiom in physics or physiology more certain than this—that the even tenor of the stream prolongs life, preserves health, and maintains happiness; while, on the other hand the strong excitements, whether of body or mind, afford temporary enjoyment, at *the* expense of permanent sufferings. It is true that the elasticity of youth and health, renders the penalties of indulgence short at the beginning, and amply repaid by the pleasures of the feast, whether intellectual or corporeal. But the periods of enjoyment gradually shorten, while those of pain are protracted, till at length a balance is struck that awakens the delinquent to a frightful survey of the real condition in which he is placed! It is then, in general, too late to retrace our steps.

"Now the besetting sin of the present generation is not that of intemperance in eating and drinking—but rather in that of reading and thinking. And why is this? When the intellectual powers are much exerted, the physical powers, and more especially the powers of the digestive organs, are weakened. Hence we have neither the relish for gluttony nor inebriation, nor have we the ability to bear their effects. Add to this, that the exercise of the rational faculties dissuades from intemperance, independent of withdrawing the power of indulging in it. In rude states of society, where the higher functions of the mind are but little employed, the sensual gratifications of the palate and stomach constitute the principal pleasures of life—and the organs being strong, these pleasures are exquisitely enjoyed, and borne with comparative facility. The coal-heaver, on the banks of the Thames, whose brain is nearly as inert at the sable load under which his muscles crack, will drink ten or twelve quarts of porter, besides gin, in one day, and go home as sober as a judge at night. But let the JUDGE himself, whose active brain absorbs all energy from his muscles, try this experiment!

"Here, then, is the true solution of the problem—the real causes why the present generation are more temperate than their ancestors—namely, disrelish for, and inability to bear intemperance, as compared with those of the olden time. But the effects of intemperance have not diminished in proportion. On the contrary, they have multiplied prodigiously. What was ultra-abstemiousness a hundred years ago, would now be destructive excess. The habits and manners of the hardy Highlanders, in the days of Waverly and the wassail bowl, would ill suit the natives of Glenco and Tobermory in the present day. Tea, politics and steam, have wonderfully impaired the digestive organs of the Celt and Sassenach laird since the days of Bradwardine and Tully-veolan, though, some of their descendants appear to have, even yet, their stomachs lined with copper, and proof against the fiery impressions of the most potent Glenlivit!

"Thus, then, a nervous temperament—a morbid sensibility—pervades the whole frame of society, more or less—a supersensitiveness that inflicts pains and penalties on trifling and occasional indiscretions, which used formerly to be levied only upon habitual and excessive indulgence! There are many millions in this country to whom food is physic of the bitterest kind—and to whom physic is daily as indispensable as food! To the luxurious epicure it may seem incredible that, within the boundaries of the British isles, there are millions, among the opulent classes, who would give half their wealth to be able to do without food altogether—who would gladly give up the pleasure of *eating*, for an immunity from the misery of *digesting*. Incredible as this may seem, it is nevertheless strictly true.

"I wish I could state, consistently with truth, that the punishment falls exclusively on the intemperate—that the gourmand is the only victim, in the end, of indigestion, and all its indescribable horrors. But I am compelled to aver that this penalty falls far more frequently on the innocent than on the guilty—on those who labor with their heads for the good of society, rather than on those who consume the fruits of the earth in luxury and idleness—on the unfortunate far more often than on the offender."

We invite the tillers of the soil, who have the healthiest employment given to man—who may, without prejudice, blend the pleasures of intellect with the healthful robust labors of the farm—to peruse the preceding article with attention—and to remember that it comes from one of the most eminent physicians of the day. How many young men, whose health is considered too delicate for farm labor—are sent to studious and sedentary employments—the very situations, above all others, calculated to aggravate the malady, and to shorten life! How many are there, who, under a mistaken notion of adding to their happiness in life, are sent from the farm to the counter, the bar, the pulpit, &c. with the almost moral certainty of rendering them the premature victims of disease and wretchedness! Study, it is here seen, is deleterious, when its effects are not counteracted by due *exercise in the open air*, and by *temperance* in the indulgence of the appetites and passions. The farm—the farm—is the place, above all others, where the blessings of health, and the pleasures of intellectual enjoyments, are to be found most happily combined.

EXCULPATORY.—From the information we have received, we feel bound to exculpate the Rev. Mr. Abeel from any sinister motives in the part he has taken in getting up common school libraries. On the contrary, we are assured, that he has devoted much time and money to promote the undertaking, without the expectation of ultimate reward.

CORRESPONDENCE.

Cutting Corn Stalk Fodder—the Grub Worm—Doctoring Fruit Trees—Root Culture.

Williamstown, Mass. Dec. 20th, 1838.

Hon. J. BUEL—Dear Sir—I have not the happiness either to bear the honorable title, or to share the enviable labors, of the *professional farmer:* yet, having been accustomed in early life to the occupations of the field, for which I still retain a relish, and having made it for several years my relaxation to supervise the general conduct of a little farm, whose details are carried out by proxy, my sympathies are in a measure with the cultivators of the soil, and I feel a sufficient degree of interest in whatever pertains to the *improvement* of any branch of the great agricultural economy. That material advances have been made within the last few years in this most ancient and important of all the arts, I think, admits not of a doubt; and that the most considerable agent in effecting such a change, has been the prevalence of *mutual information* during this period, I hold to be alike unquestionable.

Entertaining opinions like these, it will not be thought strange if I feel an inclination to contribute *my "mite,"* (if indeed I turn not out to be more *miteless* than the "widow,") towards the still further promotion of what has been by some denominated "book-farming." It is in compliance with such an inclination that I submit to your inspection the following items, the "raw material" of which I find in my "Farmers' Journal." If you deem them of consequence enough to merit a place in your columns, please to present them to your readers; if otherwise, give them a place among such other "crums" (unfit for "the dogs,") as you cast under your table, and pardon me for inflicting upon you the misery of giving them a bootless perusal.

Item First—Cutting Corn Fodder for Cattle.

Having occasion, about the middle of November, 1836, to pass through your city, and stopping for an hour at Bement's Hotel, I had an accidental opportunity of witnessing the operation of a "Green's Straw Cutter;" and so well was I pleased at first sight with its execution, that I proceeded immediately to Thorburn's and made a purchase. Feeling a *little bit streaked*, as "Slickville" would say, after getting it home, lest some of the more "knowing ones" among my neighbors, should take it into their "bump of self-esteem" to underrate my wisdom in parting with "thirty round dollars for a little machine," which Sampson would have pocketed just in the way we common folks do a jack-knife, I made some haste to get it into effective operation, working up hay and straw for my horses, and stalks for my cattle. Of this latter article, I had on hand the produce of some 4½ acres, heavy growth, and I directed my man to prepare of it daily a quantity sufficient for the *keep* (your pardon, Dr. Webster,) of five cows; which quantity proved not to vary much from ten bushels, and occupied in the preparation from one to one and a half hours per day. On this allowance, with pretty uniformly a little oat straw in the yard at noon, my cows were kept until some time in April, when the supply was exhausted. I never wish to have my cows winter better. Of the fodder thus prepared, (cut simply, and neither brined, salted nor steamed,) and fed to them in mangers in their stalls, they consumed, by measure, five parts out of six; the rejected portion consisting entirely of the largest *buts*. These were thrown daily into the yard, as refuse; a measure to be placed entirely to the score of mismanagement, for had they been left in the mangers, and the allowance shortened a little, I am since convinced, they would have totally disappeared.

At one and a half hours per day, for four months, the *time* consumed in preparing the fodder amounts to seven and a half days; which, at four shillings per day, will make the *expense of cutting* $5. The *saving in the fodder* cannot be fairly estimated at less than one-third of the whole, or the entire keeping of 1⅔ cows (so "Colburn" cuts up cattle,) for four months. This being equal to the keeping of one cow for 6⅔ months may be quickly set down at the current value of two tons of good hay, say $20. Clear profit, $15. But this is not *all*. The *improvement of the manure*, consequent on this mode of feeding the stalks, instead of casting them *whole* into the yard after the common practice, is of itself almost an equivalent for all the extra expense.

The 1st of December, 1837, I commenced in the same way, on the produce of four acres, (very heavy growth of the large Dutton,) except that I fed it to 20 two year olds. These had previously eaten no hay, and I instructed my man to keep them rather close for the first few days, in order to induce them to clear their mangers. In this I succeeded so completely, that at the end of feeding the stalks, I could say without hesitation, I did not believe, that of the whole supply, *a pound to the ton* had been wasted by *rejection.* From beginning to end, a single shovel full of leavings had not been removed from the mangers, and *at* the end, a shovel full could not have been obtained from them. These cattle were also allowed a little straw once a day in the yard. A short time previous to their commencing on the stalks, they were purchased in the neighborhood, at $17½ per head. When they had finished them, some two months after, I could have readily sold the whole of them at $25 per head. Advance on their aggregate value, $150. I have not yet been *laughed at* for purchasing the Straw Cutter; and should I, by any accident, be deprived of the one I now have, I would run the *risk* of being laughed at, and pay $100 for another, could I not obtain it cheaper. I understand, however, that the price of the article is getting *reduced,* in which I very much rejoice, as I should like to see it introduced *generally.*

I should have remarked before, that my stalks are uniformly cut *at the ground,* which practice of course I fully approve. The largest buts are cut without difficulty, and in no way injure the knives of the cutter.—These I have hitherto been under the necessity of sharpening no oftener than once in twelve months, though the amount of work done by them, in hay, straw and stalks, has amounted to not less than from ten to fifteen or twenty tons per year. To facilitate the operations of the machine, I annex to it a *false* apron for the purpose of receiving the stalks, the *true* one being of insufficient dimensions, and occasionally *clear the spaces between the knives,* with an instrument kept at hand for this purpose.

Perhaps, from what has been advanced above, I may be thought by some to have a *strong motive* for recommending "Green's Straw Cutter." I certainly have, sir; and an equally strong one for speaking in favor of any *other* cutter that will do the same execution, and consequently afford the same profit to the owner. The only inducement I have to say a word in favor of *any* machine of the kind, is to be found alone in the results of the above detailed experiments.

Item Second—A great Enemy to Corn,

as many a desolated field of the last season can bear me witness, is the cut worm, or black grub. To prevent the depredations of this unwelcome visiter last spring, I caused each hill of my corn. immediately after planting, to receive a common handful of good *live ashes,* and another immediately after weeding. This proved, however, to present no obstacle to the progress of the enemy, and I soon discovered that my whole field was more than decimated, and the work of destruction advancing briskly. I therefore ordered my men, as a last resort, to "prepare for *war*"—to "sharpen their finger ends," and set at once about exhuming the marauders. For several days it seemed as if "a whole procession came to each one's funeral," but at length victory wreathed the brow of perseverance; and the precaution having been taken to replace each foe dislodged with a suitable quantity of good seed corn, I soon had the pleasure to see my field restored, in a good measure, to its original order and beauty, there being seldom a vacancy in a piece of four acres. The latest planted came to maturity, (the white flint being the variety used for replanting,) and the produce of the field was estimated at 45 bushels to the acre. Had I not pursued the course above indicated, I am confident that the average of the crop would not have exceeded 30 bushels to the acre.—By the process of "grubbing," then, I secured an increase, in the produce of the four acres, of 60 bushels of good sound corn. The time consumed in the operation was probably equal to about eight days. Eight times five Yankee shillings is $6.67. Sixty bushels of corn, at ninety cents per bushels, is $54. Difference, $47.33. From this deduct the further expenses of harvesting, &c. &c. (not forgetting, however, that the *stalks* are worth something,) and there will still be left a remainder well worth pocketing by any small farmer. I would therefore recommend it to "the profession," whenever annoyed by the above-mentioned enemy, to "go and do likewise."

Item Third—"Doctoring" Fruit Trees.

Very often does it happen that a valuable young fruit tree is sacrificed for want of a little "doctoring." Some time in the latter part of June last, a street-running cow, through the inadvertence of a lad on the premises, gained admission, just at evening, into my fruit-yard.—Attracted by the appearance of a fine Bolmer plum-tree, five years from the nursery, full of luxuriant foliage and young wood, and richly laden with its first offering of fruit, she made a rude attack upon it, broke it down to the ground, and before the mischief "got wind," succeeded in stripping it entirely of its young wood, one of its largest branches, and nearly all of its fruit. My vexation on discovering the accident was extreme. It was a favorite tree, and I had watched over its growth for years, with an unusual interest: it had now come forward into full bearing, and already had my "mouth watered" in anticipation of its exquisite fruit. But there lay my "castle," in pitiful ruins. I had no hope whatever of repairing the misfortune. So with a length of visage that bore no mean comparison with that of the luckless cow, I turned me away to comfort myself as well as I could with that wonderful nostrum "What cannot be cured, must still be endured." By the next morning, however, I had made up my mind to *attempt a cure.* "There is nothing like trying." I accordingly commenced by examining the wound. The tree was broken quite down, about two inches from the ground, and all that held the root and stock (or "soul and body") together, was a thin slip of wood, not larger, to speak safely, than my smallest finger; and even from this, *the bark was severed* for nearly three inches. A pretty bad patient, surely; however, I proceeded, raised it up to a little more than a perpendicular position, and confined it firmly, in different directions, by several thongs, made fast to stakes which I had driven for the purpose. By placing the tree in this position, I brought the bark into the closest possible contact with the slip from which it had been dissevered; and by confining it thus in different directions, prevented the winds from racking and twisting it, and frustrating my intention of reuniting the parts. I next proceeded to lay over the entire fracture a thorough coating of grafting wax, to exclude the *air,* and finished the operation by raising a cone of fresh clay loam, to the height of eighteen inches about the stock, to avert the influence of the *sun,* not only from the wax, but also from that part of the stock contiguous to the wound. To my surprise, I discovered within a week, that it was putting forth fresh leaves and new wood. This it continued to do, and even to *ripen a number of plums,* which I had left upon its mutilated branches. At length, by the middle of October, I had the pleasure to see its new wood pushed, in numerous instances, to the length of six or eight inches, and to *taste of its fruit completely matured.* Having taken the further precaution to give it another good dressing of loam, I am now fully confident that it will outlive the winter, and another spring "go on its way rejoicing."

Item Fourth—A peep at Root Culture.

On the 18th day of October last, I took from 108 feet of ground, in my garden, 7½ bushels, large measure, of mangold wurtzel, being at the rate of 3,025 bushels to the acre; and from 90 feet, four bushels of carrots, being at the rate of 1,936 bushels to the acre. This teaches me what I, J, K, or any body else, *might* do on a larger scale. Respectfully,

ASAHEL FOOTE.

English Potato Oats.

Having unexpectedly met with a small quantity of *English Potato Oats,* in Baltimore, (of which the Irish make their oat-meal bread,) and for which, I paid $3 per bushel, I tried them on my land in Westmoreland, and realized a most surprising increase. The oats I obtained from my land, are far superior to any other in *quality, quantity and straw.* A friend of mine procured *one gallon* of the oats, sowed them in drills, on a *very rich soil,* and obtained about *eight bushels from the gallon,* with an abundance of excellent straw.

G. GLASCOCK.

Westmoreland C. H. Va. Dec. 1838.

Cultivation and Profits of Potatoes.

Warren, Herkimer co. Dec. 26, 1838.

J. Buel, Esq.—Sir—Being a constant reader of your very valuable paper, I have noticed with thrilling interest the various improvements and experiments which have been made in the different departments of agriculture, and I rejoice to see such a growing interest in many, to become more intimately acquainted with the best methods of cultivating the soil, as also erecting the most convenient buildings for housing its products, so that the business may not only become pleasant but profitable to those already engaged in it, but shall induce others to embark in the same healthy and pleasant business. That I might cast in my mite into the scale of valuable experiments already published, I have been induced to send you my experience of about twenty years, of the best method of cultivating that most valuable root, the potato. When I say the most valuable, I mean as I say, especially in this region, I think it takes the preference of all. By this, I do not mean to despise any of the other varieties; they are all valuable in their place.

My way of raising potatoes is to have, first, a good fence; then clear the land from stone, and either fall plough, or plough early in spring, as soon as the frost is sufficiently out. Here I would remark, that very late fall ploughing is not as good, in general, after my manner of preparing land, as early spring ploughing, for this reason—whatever you turn in late in the fall, when the weather becomes cold, settles down in a hard state at bottom, and there remains dead, but not rotten, until it is turned up to the air. If I fall plough for the potato crop, or any other, where it is to be ploughed again in the spring, I choose to plough the fore part of September, when the ground is yet warm, so that the process of decomposition of all the vegetable matter, may at least be commenced before cold weather; then when you turn it up in the spring, it is in a suitable state to be food for the plants. I am much pleased with the mode of keeping debt and credit with certain crops, and I shall take the liberty of sending you a statement of the profits from a piece of ground planted with potatoes; and herein your readers will see my manner of cultivating the potato in full, which mode, as I said before, I have practised about twenty years, and shall continue to practice, until some of your numerous readers point out a better method, or I find out such, by actual experiment. If any of your readers should be willing to try the experiment, and will give the result in your valuable publication, I shall be richly paid for all my trouble:—

Potato Field,	*Dr.*
To 1½ days ploughing first time,	$3 00
To 1 day with team dragging,	2 00
To 2 men, boy and team 2 days, drawing and spreading manure,	5 00
To 70 loads long manure at 2s	17 50
To ploughing 2d time,	2 00
To 2 hands and team fitting ground and planting,	2 50
To bushing, cultivating and ploughing, 1 horse,	1 25
To 2 days hoeing,	1 25
To 7½ days harvesting,	5 62
Interest on land at $50 per acre, 1½ acres,	4 25
	$44 37
Cr.	
By 600 bushels potatoes at 25 cts	$150 00
Deduct cost,	44 37
Profits,	$105 65

This piece of ground, my neighbors tell me, had been under the plough ever since the land was cleared, say 25 or 30 years, and was apparently completely exhausted, or worn out, as some of my neighbors told me, and as the crop told previous to its coming into my possession, five years last spring. I cleared off the stones, ploughed very deep, sowed with barley, without any manure, had a tolerable crop; seeded with clover and timothy, mowed it for hay, year after year, till last year, when I fall ploughed a part, and the rest early in spring, let it lay till some time in May, then harrowed it thoroughly, then drew on my manure, spread it and ploughed it in; then dragged the ground until well pulverized; then about the first of June, planted. My method is first to take my corn marker, with three teeth, two feet eight or ten inches apart, mark the ground one way, so that the rows may not only be straight, but all at one exact distance, then furrow with a light plough in the same marks, then take my marker and cross the furrows, so that every hill stands at an exact distance. When the ground is thus prepared, commence dropping the potatoes the same way the ground is furrowed, observing the cross marks, so that the rows are straight both ways, at the same time treading on every potato, to prevent them being removed out of the place by the horses; after two or three rows are dropped, I take my team and plough and commence covering, by turning a furrow each way on to the potatoes; in this way, two of us with one team, furrowed and cross marked, dropped and covered, the 1½ acres I have described, in one day, taking all the potatoes at the same time from the cellar.—Here I would remark, by the by, that land that lies high and dry we calculate to furrow to about half the depth of soil broken up; but on flat land that lies rather low, furrow very shallow. In this way of planting, there are several advantages over that of covering with a hoe; first, the labor is much less; secondly, you stir all the ground; thirdly, you cover them much better; fourthly, you throw all the soil and manure on the rows, and fifthly, if your ground is wet, these furrows receive all the surplus water, and leave the hills dry.—In this way we have never suffered any loss when we have planted on flat low ground, while I have known many of my neighbors suffer very much by having their potatoes immersed in water, and rot in the ground.—Another advantage over that of covering with a hoe is, in after tillage, when covered with a hoe, there is no way of cleaning the hills from weeds but with a hand hoe; but in our way, you will observe, there is a ridge thrown over the row, and just before the potato shoots through the ground, we take a good heavy bush and cross the ridges, which sweeps off every vestige of weeds, grass, small stones or lumps of earth, and drops them in the furrows between the rows, leaving the hills perfectly clean, and at the same time leaving the ground light and mellow. As soon as the potatoes are up, so that we can follow the rows, we cross the rows with a cultivator, or, if destitute of one, take a one horse plough and go as near the potato as possible, without disturbing it, so that the ground may be kept light and mellow; after six or eight days, we go through with the same process the other way; after six or eight days more, we take our two mould-board plough, or horse hoe, as some call it, and go one furrow in a row, or between the rows, leaving them thus till the potatoes are of a suitable size for earthing for the last time, and this must be done before the tops begin to fall, or set for blossoms; then we go through the other way with the plough for the last time, and the tilling is about accomplished. We generally go over them lightly with a hand hoe, but this part of the labor is soon accomplished. In our field, this year, we left three rows without using a hand hoe at all, either in planting, or hoeing for an experiment, and when harvesting, we dug two of the rows where the hand hoe was not used, and two of the others adjoining, measured them exact, and found there was no difference perceivable, except in a few hills falling a little short, in consequence, as I suppose, of laying through a small piece of quack grass. On the whole, however, we think it best to go over the ground with a hand hoe, and just haul up the earth from each side of the hill lightly, leaving it flat and broad, so that the potatoes may have all the advantage of dews and light showers. The manner in which some hill their potatoes, we think very injurious; in some seasons, the earth being thrown up in the form of a coal-pit, such as we used to make when we were boys, very sharp at top, gathering the tops or vines into a small compass, and thereby retarding their growth, and barring them from receiving any benefit from dews or showers, unless they come in copious effusions.

And now I have given you, in as concise a manner as possible, my manner of cultivating the potato, which I think has the decided preference of any other way, that I have ever learnt, both in labor saving as well as in product and tillage. One thing, in preparing the ground, slipped my mind, that is, when I spread my manure, I sow on plaster before ploughing in, at the rate of 1½ bushels to the acre, which I think very beneficial where your manure is very long, and in that way it helps in some way or other to decompose it, so that it more readily mixes with the soil, but how I am unable to tell; but that it does, in some way, I am pretty certain. I have practised it several years. Two years since, I omitted sowing any, for an experiment, and I do not wish to try it again, as it gave me much trouble in clogging my plough, and when I have used plaster, I have had none of this trouble.

If, sir, you should think this worthy of a place in some corner of your valuable paper, and will in any way benefit the agricultural interest, I should be pleased at some future time to give some further experience on the same subject. Respectfully yours,

EBEN. W. FRENCH.

Remark.—We are free to say, that we think the management of the potato crop, as described above by Mr. French, is the cheapest and best mode that can be adopted; and although the details may to some appear tedious, they are well worth reading and being treasured up. The effect of fall ploughing, Mr. F. remarks, is to cause the land to settle down into a hard state at bottom. We suspect Mr. F. turns a flat furrow. If he would lap his furrows on to each other, in an angle of 45°, every furrow would form a drain for the water, air would come to the sod, and the bottom would not become hard; yet it would not rot, with air and moisture, until aided by a warm temperature.—*Cond.*

Salting Calves.

J. Buel, Esq.—Dear Sir—Early in autumn, I visited Mr. Samuel Look of West Schuyler, Herkimer county, N. Y. who showed me many things connected with his large farming establishment, which are worthy of record, and to be practised by others. Mr. Look is well known to be a skilful agriculturist and herdsman; but it is as the latter that his qualifications are pre-eminent. Among the many useful contrivances, is his method of *salting calves.*

As soon as his pumpkins become sufficiently ripe for the purpose, he takes a quantity equal to half the number of his calves, divides them through the middle with a knife, and lays them on the pasture ground where the calves run, with the core uppermost; into these, he sprinkles as much salt as the calves require at one time. This kind of trough is not recommended for its durability; it will not generally last longer than two or three days; but Mr. L. says this should be no objection to their use, as they are easily replaced, and he adds, he never knew calves to be injured by devouring troughs of this kind; on the contrary, he thinks the more of them they swallow, the better they appear. A large portion of his stock consists of the improved short horn breed. Mr. Look, at this date, has some half a dozen bulls, and a few heifers of this sort, all bred from some of the best families ever imported, which he would sell.

Yours, &c. N.

Butternuts, Dec. 31, 1838.

Brining and Liming Seed Wheat.

Trenton, Oneida co. Dec. 14, 1838.

J. Buel, Esq.—Sir—Having observed in the Cultivator, some difference of opinion as to the effect of brining and liming seed wheat to prevent smut, hoping by stating to you the little experience, I have had on the subject, I may do no harm, but be of some benefit, is my excuse for addressing you at this time.

It has been the practice among farmers in this region for something like forty years, to wash and lime their seed wheat to prevent smut. Having noticed in a newspaper, nearly thirty years since, an account of a vessel loaded with wheat having been sunk on the coast of England, and before it could be taken out was so saturated with salt as to render it unfit for bread, some of it was used for seed, and where that was sown, it was observed there was but little or no smut, while in the same neighborhood, where other wheat was sown, the wheat was quite smutty, which circumstance led to the practice of using brine for seed wheat. Seeing that lime and salt, when separately applied, were beneficial to prevent smut, it occurred to me, if both were applied at the same time, the remedy might be effectual. I accordingly adopted the practice of washing my seed wheat in a brine as strong as can be made, stirring it until thoroughly wet, say from five to ten minutes; drain off the brine and spread the wheat on a floor; put on slaked lime that is dry, (when a sufficient quantity of wheat is washed,) four quarts to a bushel is sufficient; work it over with the hoe and shovel until each kernel is covered with a good coat of lime; then spread it over the floor to dry several days before sowing—the drying is necessary to prevent the moisture of the ground causing the lime to cleave from the kernel before the harrowing is finished. There is no danger of injuring the wheat by its lying after being limed—have had it lie two weeks or more—and have never been troubled with smut since the above mode of preparing seed was adopted, and am firmly of the opinion, when the seed wheat is well prepared as above stated, the remedy against smut will be found effectual. The circumstances stated by J. Hathaway, Esq. last spring, of his neighbor having sown some of his wheat soon after liming, and was prevented from sowing the remainder for several days on account of rainy weather—the former being some smutty, while the latter had little or none—I think goes to show the benefit of letting the wheat dry before sowing.

Others may have prepared their seed wheat in the manner above stated before me, but I had never known an instance. After having prepared seed wheat as above for several years, and being satisfied of its good effects, I sent an account of the above mode of preparing seed wheat, to the editor of a newspaper in Utica, Mr. Maynard, I believe, which he published about twenty years ago. Yours very respectfully,

JOHN STORRS.

Mode of Curing the Hoof-Ail.

Paine's Hollow, Jan. 12, 1838.

Mr. Buel—Sir—In the current volume of your Cultivator, at page 55, you have said something on the subject of the poison of the ergot on rye and the grasses, both to man and brute, which would be of great use to the farmer, if he would follow your suggestions in alternating his crops and seed down thick with the more healthful grasses. There is no doubt but the ergot on the grasses produces the hoof-ail in our cattle. I will here give you my treatment of that complaint, which I have never known to fail in a single instance. When I find one of my cattle has this complaint, I put it in the stantials in the stable, then take a mallet and a carpenter's chissel, and set the chissel on the toe of the hoof, three-fourths of an inch from the point of the hoof, then with a brisk blow of the mallet, repeating the blows until the hoof is cut off; if it does not bleed freely, take a thin shaving more, and so continue until the blood runs freely; no matter if the small artery in the point of the toe is cut off, the blood will stop in fifteen or twenty minutes; if the creature should prove refractory, let an assistant take and hold up the opposite foot, which will make it stand firm on the floor, and stand still through the operation; this being done, it is only necessary to keep them in stable two or three days, to keep them out of wet and mud, and in six or eight days the creature will walk about as well as ever. I have never failed in a single instance of effecting a cure on any of my cattle. The sooner it is done the better, as there will be less danger of their freezing, which is worse than the hoof-ail to cure.

In 1836, I raised from one seed of the potato ball 26 potatoes, 14 of which were as large as eggs; last spring I planted the same, and last fall dug a crop of more than two bushels, of a round white potato. How many years will it take to bring them to full maturity?

Yours respectfully, THOMAS PAINE.

Brining Seed Wheat—Cure for Stifle.

Lawrenceville, Tioga co. Pa. Dec. 27, 1838.

Mr. J. Buel—Dear Sir—I think I may safely say I have discovered the cause of Mr. Hathaway's brined spring wheat not coming up well, to be owing to the smut machine and brining also. This fall, my wheat being some chessy, I took it to the mill to have it screened, and as that and the smutter were connected, the wheat had to pass through both; after which I brined the most of it, from 12 to 18 hours, then limed and sowed immediately.

Not brined or limed came up well, though it had been through the smutter.

Brined 18 hours, then limed, came up badly if smutted.

Brined 18 hours, and having passed the smutter twice, not one kernel came up.

Brined 12 hours and once smutted, came up pretty well.

Brined 18 hours but not smutted, all came up fine.

Inference—the smut mill opens the grain in some way so that the brine kills it.

The grain worm has made its appearance here the past season, though not extensively.

I will here give you a receipt for curing a stifle, which I consider invaluable, and as for its being infallible, I think no man can gainsay it. At any rate, I have cured many horses, and sold the receipt for many dollars, thus:—

A handful of sumach bark and a handful of white oak bark, boiled in a gallon of water, down to two quarts; bathe the stifle with this lotion twice a day for three days; then put on a salve made of the white of an egg and rosin, and bathe the same in with a hot shovel two or three times, and the horse is cured. Yours with esteem and respect,

W. KILBURN.

Experiment in the Culture of Rape.

Hill-Side, (near Meadville,)
Crawford co. Pa. Nov. 29, 1838.

J. Buel—Sir—By referring to vol. 3, p. 110, of the Cultivator, you will find the following remark, in reply to a Mr. Davis, of Saratoga, on the culture of "Rape, colze, or cole seed," viz:—"An important article in Flemish husbandry, &c. though not at all cultivated in the United States." * * * "As rape is biennial, it is doubtful whether it would withstand the cold of our winters." If of interest to you, I take pleasure in communicating as follows:

Mr. Frederick W. Kockler, of this county, lately imported from Holland, some rape seed; he sowed three-fourths of an acre in August of last year; the produce in seed this year, amounted to twenty bushels, although the seed was not taken at all clean from the stalks, and the land was very illy tilled for this crop, as well as for the previous crops taken from it. The produce would have been thirty bushels undoubtedly, had the crop been properly harvested. The crop was taken in on the 12th day of July. The rape stood the effects of the last severe winter well; it was uninjured, although grown in an exposed situation. According to Mr. K. who is an experienced cultivator of the article, the rape seed is committed to the ground on the 24th August, in Holland—the 12th of August, he thinks late enough for this climate. He thinks that in rich, dry and well wrought soils, no crop could be more profitably cultivated in this country, and in the western states especially. In Holland, they have hard winter freezing, but not much snow, which characteristic corresponds with the climate of some of our western country. The cultivation of this crop, has been successful in some parts of Ohio, and only discontinued from want of oil mills convenient sufficiently to make its culture profitable. The above communication would have been made to you by Mr. K. himself, but he feared that his slight acquaintance with our language, would have made his communication somewhat unintelligible to you and your readers.

If I recollect right, the subject of rape culture is treated of by that enterprising gentleman, Col. John Hare Powel, of Philadelphia, in a communication to the Pennsylvania Agricultural Society, some years since. You probably have the volume of "Transactions," and can by reference discover whether it is of sufficient import to copy. I will mention here, (although foreign to Mr. Kockler's expectation,) that a few bushels, say eight or ten, of the seed, can be had of him, delivered in Meadville, at four or five dollars per bushel, which announcement, I hope, will not injure the usefulness of the intelligence contained in the general statement.—His object in dictating was not to bring his seed into market, but simply to make public his experience, in a branch of agriculture comparatively new in this country, but of great importance to our agricultural interests. Mr. Kockler will take pleasure in communicating his experience in this matter, in both Holland and this country, to any who think it of sufficient consequence to address him on the subject. Respectfully,

JOS. C. G. KENNEDY.

Making Pork.

The business of fattening pork for sale is practised to some extent by many farmers, and when performed economically, it is a source of profit; yet all will admit, when carried on in the manner it often is, it drains instead of replenishing the farmer's pocket. To make fattening swine profitable, it is necessary, in the first place, that the breed of swine should be good. There is a vast difference in swine in the respect of fattening, proper proportion of bone, weight, &c. There are several good breeds of pigs now in the country, and any farmer who is willing to make the effort, may have a lot of fine looking pigs, as well as to have long-nosed, slab-sided fellows. The time has gone by when a pig must be kept four years to weigh four hundred. The business of fattening swine is little understood, and poorly attended to. Pigs a year and a half old should come up to that, and some have exceeded that weight. Next to a good breed, it is necessary that they should be kept in a thriving situation. There must be some foundation for fattening, when the process commences, or much time will be lost, and food consumed, in making a carcass to cover with fat. Swine should have a field allotted to them, so large in proportion to their numbers, that their grass feed will be fresh. They should have the slops of the kitchen, whey of the dairy, &c. in addition to their grass feed through the summer season. The manner in which their food is prepared and given, has a decided influence on the fattening process, and of course on the aggregate profit. If given out raw, much of the value of the article is lost. Grain is much improved by grinding, but the full value is only brought out by cooking. Corn is the best article for fattening swine; yet there are but few who fatten their swine altogether on corn. I will now inform you of my manner of fattening swine the year past.

My swine were kept in a fine growing state through the summer season; and in the fall I enclosed in dry warm places ten pigs, a year and a half old, with the exception of one two years and a half old. I commenced feeding potatoes boiled dry, and then added the dairy slops. This I continued through the month of September. Then I mixed oats and barley, equal quantities, had it ground into meal, and mixed this with the potatoes boiled, and continued this through the month of October; and then I added corn with the oats and barley, equal quantities, ground together, added to the potatoes, and continued this food until I slaughtered them, which was the 26th of December, and the weight of each was as follows:

1	sow	2½	years old,	535lbs.	raised 10 pigs this season.	
1	do	1½	do	564lbs.		
1	do	1½	do	625lbs.	raised 5 pigs this season.	
1	do	1½	do	485lbs.	raised 3	do
1	do	1½	do	383lbs.	raised 3	do
1	barrow	1½	do	445lbs.		
1	do	1½	do	425lbs.		
1	do	1½	do	519lbs.		
1	do	1½	do	456lbs.		
1	do	1½	do	516lbs.		

Total pounds weight, 4,953

NEWTON WILCOX.

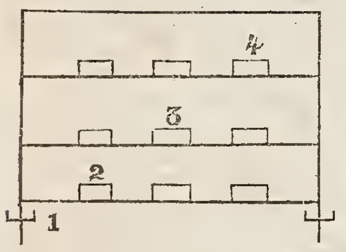
West Winfield, Herkimer co. N. Y. Jan 4, 1839.

Kentucky Bee-House.

Pleasant Hill, November 30, 1838.

Mr. J. Buel—Dear Sir—As I have sufficient room in this letter, I will give you a description of my father's Bee-House, which I think preferable to any I have seen, on account of its cheapness and convenience, and if you think it worthy of a place in your excellent periodical, it is perfectly at your disposal. The building is twelve feet long, eight wide, and seven feet high from the floor to the plate or ceiling, (the floor being eighteen inches from the ground,) and consists of four posts eleven feet six inches long, let in the ground three feet, which is weather-boarded round, and covered in, so as to prevent the bees from getting in the house, they being confined in six boxes, three on either side of the house, placed fifteen inches one above another. This drawing (Fig. No. 68,) represents one side of the house, viewed from the outside.

[Fig. No. 68.]



[Fig. No. 69.]

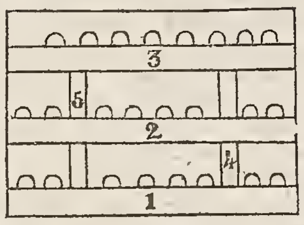


Fig. 68, No. 1, 1, are copper troughs running round the post, half way between the floor and ground, which are kept filled with water, to prevent ants or other insects from getting in the house. No. 2, 3 and 4 are tubes eight inches wide, one-eighth of an inch deep, to convey the bees through the wall into the long boxes, and entering them at bottom, there being three to each long box.

The drawing, Fig. 69, represents one side of the house, viewed from the inside. No. 1, 2 and 3 are long boxes, eighteen inches wide and twelve deep, extending the whole length of the house, with eight holes, four inches square, in each box, upon which is set two gallon caps, with two half inch holes in each, one near the top, the other about the centre of the cap, in which the smoke of a burning rag is blown to drive the bees from the cap into the long box, which can be known by striking the caps. When they are all in the long box, a knife or wire should be drawn under the bottom of the cap, to separate the comb from the box, when the cap of honey may be removed, and an empty one put in its place. No. 4 and 5 are tubes three inches square, to convey the bees from one box to another, that one swarm of bees may do the whole, or if one or more swarms be put in each box, that they may become as one, as they will not permit more than one king when put together, by which they are prevented from destroying themselves by fighting.

A house of this description, when the long boxes are filled, will afford, at a moderate calculation, ninety-six gallons of honey in the comb annually.

F. S FISHER.

Matters of General Interest.

Hartford, Dec. 27, 1838.

My Dear Sir—Minutes, hours, months and years, seem to me much shorter than they once were; formerly, I had leisure enough, or at least thought so, for I have wasted many an hour impatiently waiting for the coming time, and now all my industry avails me little; my good intentions unperformed accumulate from day to day, till nothing short of an expunging process can set me free. I however took good care to wipe away no part of my debt to you, as it involved too much of interest to myself to be otherwise cancelled than by a letter. It is scarce necessary I should express my regret at not meeting you—my endeavours to do so will best testify on that point; that pleasure must now be deferred till February, when I have made my arrangements to be present at the State Agricultural meeting, together with one or two gentlemen from this state. This reminds me of your half promised circular which I have expected with some impatience—I hope you do not feel discouraged, but that an Agricultural School will, ere long, be established; it seems to me the next step to be taken in the path of improvement—its effect will be most beneficial and enduring; and if it be slow it will be silent as well as irresistible in its influences, for they will flow through channels that are less jealously watched and freer from suspicion than any legislative act; for what can be done for the man who cries out "I will die and nobody shall help me"—a blunder, I allow; but not a greater or more fatal one than the Farmer's, when he declares, "I will be ignorant and no one shall instruct me;" and then becomes vociferous about rich and poor, aristocracy and democracy, until the question of his own improvement is dragged into the *political* arena and becomes a question for the people; a field in which ignorance and prejudice can out-number, and therefore successfully array itself against intelligence and science; then comes the damning cry of, "taxing the many to gratify the few," &c. &c.—What profound ignorance! what deep cause of regret, that so *important* and so large a part of our community are so much below the standard of intelligence, found throughout every other portion of the American people. And it does seem to me that the evil cannot be reached through any of the agricultural periodicals; I continually regret that the excellent essays I there find come under the eye of those *only* who *do not* require them, for whom they are *not* intended; while the ignorant and prejudiced never see them, scarcely ever hear of them. Now it does strike me that some more certain and direct way *might* be found of addressing these truths to those who most stand in need of them, for it is not the *readers* of the Cultivator who require to be taught the value of its contents, nor the necessity of such modes of interchanging intelligence, in order to advance the general science and improved practice of agriculture. Enough then, perhaps, has been written *at* (for I cannot say to) the farmer who "don't believe in reading." And I would now rather see some inquiry made, and some suggestions offered, as to the duty of those *who do* see the columns of your valuable paper, whether we are doing our endeavour, each according to his individual capacity, to elevate the agricultural character by a friendly and frequent intercourse with our farming neighbors, however widely they may differ from us in opinion, however much they may despise our book-knowledge? Are we promoting, *all in our power*, exhibitions, meetings, clubs, and other social occasions friendly to that frequent interchange of opinions and views so necessary to progress? Do we make ourselves useful by examples of good culture, by *liberal* interchanges, and by permitting to others the *free* use and trial of such means, implements, and animals as we ourselves are employing for the improvement of our lands, our labor and our stock?—and very much else I would ask if we do, that lays fully within the compass of every individual. Or, do we pursue our own way in *manifest* disgust at the ignorance around us, feeling as though we had nothing in common with them, and making no effort to break down the partition walls of prejudice and contempt that they are every where building up? A quantum sufficit of zeal, with a little liberality towards the necessary funds of societies you wish should prosper will do much towards the desired end.

I often observe comparisons made between the agricultural spirit of this country and England; but to me they seem unfair, in as much as there is an important link not found in this country which in that connects the practical farmer with the very sources of science; I allude, of course, to the large landed proprietor of highly cultivated estates under the management of a numerous tenantry, on whose successful farming and improvements their income depends; there, there is a fostering, and tho' perhaps a selfish, care continually extended towards the cultivator of the English soil, unremitting in its assiduity, and highly influential in its character, the landlord and tenant having one and the same interest. Not that I covet, by any means, the same state of things here; I would merely draw your attention to the unfairness of comparison, and inquire how far we may obtain the same results by different and more desirable means. Take from them this powerful link, and let them drop off from the great chain, and become as the American farmers are, a part and portion by themselves, and you would soon find them even behind us as a community; for it is within my knowledge, that the then called intelligent farmers in England, who were prejudiced against the short horns, held and promulgated the opinion that crosses of the short horns on other breeds produced animals as incapable of breeding as the mule! &c. &c.

Thus you see I would extend, as far as may be possible, to the American farmer, all the *advantages* and *kindly feelings* of an English landlord, without subjecting him or his lands to any of his claims. Should you see with me in this matter, *you* may perhaps be induced to address those who *do* read the Cultivator, and by exciting *them* to greater activity in their respective spheres, at length obtain a reading from *those* who now despise book-farming; and I am strongly disposed to think, that if a farmer will once read, prejudice will give way.

I attach much consequence to the manuals of farming for which premiums have been offered, and I sincerely hope they may be what they ought to be, *and if so*, that such a fund may be raised as will afford them very cheap to the farmer; and from my observation, and I may almost say, intimate knowledge of the unreading farmer, they should be written in that simple plain style that will remove as much as possible all difficulty in reading.

When arranging our premiums, I suggested offering some of our agricultural periodicals as rewards, which was at once acceded to by the society, and I think no less than 20 copies of the Cultivator and Genesee Farmer, were included in the list; but I was sorry to find, that though we had no less than eighty well filled pens, yet there were not claimants for the lower premiums of many of the classes, consequently but three copies of the Cultivator for 1839 were claimed. We preferred awarding a *current* volume, because it would then be received in parts, be more certainly read, and more surely missed at the end of the year. Farmers have but little time to read, and often find that little reading difficult, and a volume would be laid aside while a paper would be read by snatches and at odd times. F.

Remarks—Although the above is extracted from a private letter, not designed for publication, we nevertheless feel justified, after suppressing the writer's name, in applying it to public uses. We will only remark, that it admonishes our great men—be they statesmen or landlords—of the importance of giving THEIR attention to the improvement of our agriculture—as a means both of promoting their individual and the public interest—and it shows the importance of having, in our common school libraries, books upon agriculture, as the best means of eradicating prejudice against useful improvement, and of laying the foundation of substantial usefulness in the the rising generation.—*Con. Cult.*

The Advantages of Capital on worn-out Lands.

Greene county, Va. 17th Dec. 1838.

To get rich, is to enrichen my land.

The above, Mr. Buel, is my motto. Instill this in the minds of the farmers, and the work is half done. And to the present period my motto is pretty well developed. Nine years ago, I came in possesion of my farm by purchase, which is situated at the base of the Blue Ridge. The then state of it was most chilling, but the situation much to my taste; the place, for then it could not be called a farm, no way the eye could be turned, but presented galls, gullies, broomsedge, briers, bushes, and some forty acres of wet land. The latter first engaged my attention. Within the first two years I expended $400 in ditching, and about the same amount since, which has fully come up to my expectations—having put the land in a high state of production. Secret ditches I mostly use in draining, leaving no more open than necessary, which is governed by the length of the ditch, and the quantity of water to be conveyed: if too long—and they should get choked about the source, the work will be all to do over—but this I have never had to do yet. At all times a secret ditch should convey the water; for when all of the chinks of the ditch become full, the water will spout to the surface, and drown the crop, which sometimes happen in long wet spells. My mode of secret ditching, is with rock. All other ways, such as with poles, brush, &c. are ineffectual or but temporary; but I have not yet done draining; the want of means only has retarded this improvement as well as others on my farm. Within the first four or five years of my maiden farming, the expense considerably exceeded the income, so much so, that about the end of that period I had sunk about $1200, more than half of the prime cost of my farm, which is 400 acres. At this time I was much dejected—I endeavoured to make sale, but no body was willing to add the improvements to the first cost, and the consequence was of course no sale. By this movement not a link in the chain was broke. I renewed my efforts, and have the pleasure to say, the sunk fund is all discharged, as well as some eight or ten hundred dollars worth of property acquired besides.

No person that knew my farm at the time I purchased it, but will now agree it is worth four times as much as the prime cost, and I think six times. The galls, gullies, bushes, briers, broomsedge, have all disappeared; also the rock taken off, and put into fencing and secret ditches. Not a spot, of 200 acres in cultivation, but what will produce a good crop of corn or wheat, and a good portion that was literally exhausted, will produce a good crop of tobacco; but that plant I have not yet cultivated, but notwithstanding, I am well satisfied I have increased my property much faster than the largest tobacco growers within my knowledge, in proportion to capital employed. The improvement of my farm now, is much more rapid than a few years past, and under the same management, of course, will annually increase, as well as the profits. This year it clears me about $700, from three hands; you no doubt from the above, and a self made farmer, will think it is coming on very well—and besides I will add, this farm was located upwards of a hundred years previous; of this, there is no doubt—for on a chimney I pulled down, the date of 1746 was marked upon it; and this chimney as tradition tells it, was put up by the second or third settler, and since the builder of that chimney sold it, it has passed through several owners, and all have been compelled to abandon it; and notwithstanding it has been located such a period, not an individual as yet has died the owner of it.

With these few preliminaries I stop and refer to your decision. If they prove fit for your valuable paper, more anon—if not, I will no more mix a goose quill with my ploughing, manuring and clovering, for upon these three things rest my life. Your obedient ser't.

T. G. GARTH.

Experiment in planting corn—Alternation of crops —Mode of applying Gypsum—of fattening Hogs.

Rockingham county, Va. Dec. 25, 1838.

Sir—A friend of mine, last spring, planted a part of his corn at the depth that corn is usually planted in this part of the country, and in another part of his field, he run his planting furrows unusually deep. The land was of uniform quality, and the corn in both parts covered with the common quantity of earth, so that the only difference in planting, consisted in the different depths of the planting furrows. In the early part of the summer, the corn planted in the shallow furrows, grew the best, and promised to make the best crop, but in the latter part of the summer, the season became dry, (the drought was severe,) and then the shallow planted corn began to wither, whilst the deep planted corn kept green, and continued to grow after the other was almost killed by drought, and made in the end greatly more corn. These facts have brought to my attention the question, whether corn should be planted deep or shallow? And by the question, let it be understood, that it is not a question about the depth of earth with which corn shall be covered; but a question about the depth of the furrow. And to this question, I would invite the attention of agriculturists, and request the communication of facts from all who have had any experience in the two modes of planting; as it is by a comparison of many facts only, that we can come to any safe conclusion in agricultural affairs. I have understood, that it is settled, that in the sandy lands and warm climate of South Carolina, deep planting is best. And if it shall be found that in our more northern climates and clayey soils, deep planting will yield the best crop, there is another advantage attending it, that will recommend it to those who cultivate this valuable grain. Corn that is planted deep is not so easily blown down by winds, and will not be bent and tangled at cutting time, like that which is planted on the surface. As this is a question involving no depth of reasoning or scientific knowledge, it may perhaps be passed over, with less attention than it deserves. But if it be duly considered, it will be found to be a question of interest, and it is hoped that all who can communicate facts, will contribute their aid to a correct settlement of the question. In the case mentioned above, the corn was planted in a sandy soil, of but moderate fertility, and it will occur to all that in experiments which may be detailed, the character of the soil should be given.

Another question of interest to myself, is now forcing itself upon my attention; and I would be glad to hear the opinions of those, whose experience may enable them to speak upon the subject. To state the question more clearly, I will premise that for near twenty years, I have been cultivating a small farm upon the four field system. When it first came to my hands, a part of it, though originally fertile, had been greatly exhausted by bad management, and all my efforts were directed to its improvement. My crops have been corn, wheat, clover, clover, and by a free use of plaster, and some degree of economy in saving manure, my farm is now greatly improved and may be said to be in good heart. The soil is a tolerably stiff clay, based upon what we call blue slate, the rock lying at a good depth below the surface. I have preferred mowing to grazing, and as the hoof is injurious to clay lands, the stock have been kept off the fields as much as possible, when the ground was soft. But little has been sold off the farm except wheat, clover seed, cattle and hogs.

Having but a small farm, and being desirous of cultivating more land than my farm will allow, upon the four field system, I am inclined to divide my land into three shifts, and this forces upon my attention the question, whether I can preserve the degree of fertility which my land has attained, by cultivating corn, wheat, and clover, and letting the clover stand but one year, instead of two. By letting the clover stand two years, the land has improved; and now if it shall stand but one, will the land deteriorate, and will the crop be reduced? Let it be supposed that the corn shall be fed upon the farm; that the clover shall be in part mown, and in part grazed by hogs; and that a reasonable degree of economy shall be used in saving manure.

As he who asks information from others, should be willing to communicate any which he may have, and thereby show his readiness to contribute to the common fund, I will mention, that my practice, has been to sow plaster broad-cast upon corn, instead of putting it on the hill, believing, that at earing time, which is the most important, the roots have spread over the whole surface, and that the plaster being sown broad-cast, will then be in a situation to contribute more to the growth of the corn, than it would be if placed immediately at the stock, as it is the ends of the roots that take up nourishment: and believing, too, that when sown in this way, the plaster will benefit the succeeding wheat crop, and the young clover which shall be growing with the wheat. I have indeed thought, that sometimes the young clover is thereby saved from being killed by drought.

For some years past, my attention has been turned to hogs, and having been successful in my efforts, I will give you my opinions upon that subject. The more common practice with us, is, to let our hogs shift for themselves, or to feed them but sparingly the greater part of the year, and then during the fattening season, to feed them to excess. We then attempt to do that by force, which might previously have been accomplished by an easier and cheaper process. By feeding too sparingly during the winter, the hogs are kept alive only; they do not grow; become stinted, are worth no more in the spring than they were in the fall, frequently not so much, and of course what has been fed has been wasted; and then, during fattening season, they are fed to excess, and loss is sustained by undigested corn. My plan has been to feed well, to start my pigs fat, and to keep them in uniformly good condition. They are always growing and increasing in value; are fed a small quantity of grain when running in clover pasture, and by cutting up corn for them as soon as it is in good roasting ears, they are ready for market, as soon as the weather is cold enough for slaughtering. They are, in this way, fattened during moderate weather, and all agree that hogs fatten faster in moderate than in cold weather. I prefer fattening in a field, to a close pen, and from my observation, I am satisfied the field is the best. The field is used that is intended for the corn the following year. The grass and clover roots which they get, contribute to their health, and save corn, as any one may be convinced, by observing that they will feed a part of the day on the clover, however plentifully they may be fed with corn. If hogs be well fed, and kept *dry*, and *clean*, and *warm* in winter, and be furnished with shade and plenty of water in summer, they will, I think, be always profitable. A good breed should be selected, as some breeds are certainly more profitable than others. The feeding of hogs presents another question of interest, and we ought to inquire, whether clover grazed by hogs, will improve the land as much as if it be grazed by cattle; and whether corn fed to hogs upon a field will improve it as much as if it were fed to cattle. These are questions which I would not undertake to decide from my experience, and upon which I would like to hear the opinions of others. If these inquiries shall receive any attention from the correspondents and readers of the Cultivator, I may be encouraged to trespass again upon your attention.

GEORGE H. CHRISMAN.

On Ashing Seed Wheat—The Poppy a Protection against Insects.

J. Buel—Sir—While living in the State of New-York and being a mechanic, I was a subscriber for the first volume of the Cultivator with which I was much pleased; and now having moved to Michigan, and commencing a new business with which I am unacquainted, I feel the need of instruction in this, (to me) a new branch of business: therefore I have taken the fourth, and am taking the fifth volume, and I want you to send me the sixth, and also, the second and third volumes. I think that I have been more than paid for all the expense in taking the Cultivator, in one small crop of wheat, in as much as that paper instructed me to soak seed wheat in brine, and roll it in lime; but as I had no lime, and as it was impossible to obain clean seed, I soaked it in a strong brine, and then rolled it in wood-ashes, as a substitute for lime, and to my great satisfaction, after sowing very smutty seed, I harvested a clean crop.—And I am convinced that wood-ashes is better than lime to prevent smut; and more, if wheat is soaked in salt-water and rolled in good strong ashes, I venture to say, it will never be troubled with the insect.

And now, Sir, as the grain-worm is spreading its devastation through many parts of our country, and as you have offered a premium of fifty dollars, and the editor of the Yankee Farmer, a premium of thirty dollars, for a preventive of this great destroyer of our wheat crops, I will venture to give the farmers of our country, through your columns, a preventive, or what I think will prevent the wheat-fly from hovering around our wheat crops or any other crop. If the farmer will either in the fall, or early in the spring, sow the common poppy among his wheat, he will not be troubled with the wheat-fly, unless they are invincibles indeed; for I have for twenty years sown poppies in my garden, and where they were, I have not been troubled with fly, bug, nor insect on any vegetable, even in my field among my wortzel and ruta bagas. The common poppies have prevented the ravages of all flies, bugs and insects.—And now, Sir, if I am not entitled to the above premiums, let no man look for them, for if the above is not a preventive, nothing but that power that dispersed the flies in Egypt, will disperse the wheat-flies in America.[*]

SMITHFIELD BEDEN.

Hadley, Michigan, Dec. 24, 1838.

[*] Mr. Beden's prescription shall have a fair trial.

EXTRACTS.

[*From the (London) Farmers' Magazine.*]

Essay upon the Breeding of Live Stock, and on the Comparative Influence of the Male and Female Parents in Impressing the Offspring.

By John Boswell, Esq. of Balmuto and Kingcausie.

CONCLUDED.

I would next look a little at the influence the male has in the *ox*. Here, although I still see the male have by far the greatest influence, I would say that there was a shade of difference, perhaps five per cent. less than in the horse. The cow appears to be an animal whose progeny is often much affected by her imagination during the time of conception, or rather during the period when she is in season. We have the most ancient as well as the highest authority for this in the peeled rods of Jacob: and from what my own experience, as well as the information of trustworthy men, has taught me, I am inclined to think that the calf very often takes after the beast that has been jumping on the cow (whether ox or cow) previous to her being taken to the male: One of the most intelligent breeders I have ever met with in Scotland, Mr. Mustard,[*] an extensive farmer on Sir James Carnegie's estate in Angus, told me a singular fact in regard to what I have now stated. One of his cows chanced to come into season while pasturing on a field which was bounded by that of his neighbors; out of which field an ox jumped, and went with the cow until she was brought home to the bull. The ox was white with black spots, and horned. Mr. Mustard had not a horned beast in his possession, nor one with any white on it. Nevertheless, the produce of the following spring was a black and white calf with horns. I have twice had pure Ayrshire cows, which are uniformly what is called red and white, with horns. The first of those I put to a brown bull without horns; the produce was very dark red, without any white, and polled. The next cow was put to a jet black bull with horns. The first produce was dark red, without any white, and the next was jet black, and also without any white; and in both cases the make of the progeny took greatly after the sire. On settling in the North of Scotland as a farmer, I soon perceived that one of the greatest defects in the cattle was a tendency to be knock-kneed behind, and in my endeavours to get rid of this, I procured a bull from the South of Scotland free from that defect, and with him crossed the best looking cows of the country. I instantly got rid of that narrowness behind observable in all cattle where no attention has been paid to the breed; and, in a few years, by drafting such queys as did not please me, and breeding only from good shaped ones, I made a breed for myself, which I had done before I knew it, for, having one season lost almost all my own calves, I was, in consequence of this misfortune, forced to buy in calves. These were treated in the same way as to food, &c. as my own, yet those from my own cows soon shot far a-head of them, both in size and condition; and on examination of the two sets of animals, an evident superiority of form existed in those of my own, especially in the smallness and beauty of the head, with a prominent eye; and, a fact not hitherto mentioned, that of the tail being one-half less as to thickness than in the unimproved breed, while a wide chest (that unerring sign of a good and quick feeder) was very conspicuous.[*] It would seem that horns had been given to the cow by Nature, and that the polled breed have been procured by selection of some of those varieties we so often see, as I observe that it more frequently occurs, when a polled bull is put to a horned cow, that the produce resembles the mother in that particular, than when a horned bull is put to a polled cow, when horns are almost always the consequence.[†] A great many years ago, the present Sir Alexandar Ramsay, of Fasque, brought a few of the Lancashire cattle to Scotland, a breed then much in fashion, and, as every one knows, remarkable for having uncommonly wide spreading horns, and all with some white, especially on the back. These cattle were intermixed with the cows of the country; and when Sir Alexander came to his estate, the cattle were all horned. About that time the polled or dodded cattle came greatly into vogue in Angus; and Sir Alexander purchased, from time to time, jet black polled bulls, so that in a short time all his cows were of this sort. Nevertheless, every year, even to this day, one or two of the calves "cry back" to the Lancashire, having white, and horns; and, what is singular, it is almost invariably in the male that this takes place.

An instance of the influence of the male in the progeny of the cow is narrated by Bewick, the natural historian. He is treating of the original breed of wild cattle which still exists in a few parks belonging to noblemen in the north of England, and in one or two places in Scotland. They are uniformly pure white, with black, or sometimes red ears and noses, and always extremely wild and fierce. At Chillingham Castle, in Northumberland, says Bewick, cows used frequently to be turned into the park when in season, which were covered by the wild bull; and what is strange, the produce from all those cows were uniformly white, with red ears and noses, and greatly partook of the character and qualities of the wild bull. Here, then, is a very strong proof of the influence of the male parent, and others equally strong could be quoted, did I not think it better to pass on to another animal, the *sheep*.

Here the influence of the male parent is most striking. I have stated in a former part of this essay, that I have been in the habit of purchasing a couple of scores of Highland ewes every year, to put to the Bakewell ram. Let us look a little at the characteristics of every breed in a wild, or at least nearly wild state. We find them muscular, active, restless in quest of food, ever in motion, and refusing to lay on fat.[‡] Such I found the Highland ewes; they were all small, with black legs and faces, and had horns. On being put to the Bakewell, they produce lambs of a totally different breed from themselves, all having the greatest tendency to get fat, the wild wiry appearance of the Highlanders being entirely gone; and in its place we have a round fleshy animal, resting peaceably in the fields, the desire to break over fences having likewise disappeared; and what is remarkable, not a single lamb is to be found with black legs or a black face, and scarcely one with any sort of horn,[§] while all are of a very large size. They thrive remarkably well, any that I have allowed to grow up as an experiment; and I have always found them much more free from disease than either the Bakewell or the black-faced sheep, particularly the rot of the liver, which makes dreadful havoc amongst the Bakewell; nor does it spare the Highlander, especially when put on high keep. I cannot speak much of the appearance produced by a Highland ram with the Bakewell ewe. Being fully convinced of the power of the male on the offspring, I have always accounted it as loss to put a bad male to a high bred female, and have never done so. I have, however, observed, where the country people have purchased high-bred sheep at any sale of mine, and bred from them with the ordinary rams, that the breed very quickly got bad; whereas when a Bakewell ram had been purchased, I have seen a most remarkable change on the quality of the sheep; and in several instances where the ewes had been tolerable from which they had bred, the cross was so nearly resembling a new Leicester, as to deceive any one who was not a thorough judge. As I wish to confine myself to facts which have come under my own observation, I shall forbear to mention circumstances which tend to prove the great power in the male as to influence in the progeny of the ewe, as I have them from others; and shall conclude with the *sow.*

---

[*] This gentleman's stock are all jet black and polled, and so remarkably alike, that they show much care in attending to the breed.

[*] "An observation which Dr. Jenner made to me about ten years ago (the truth of which has been since confirmed by my own experience) that no animal whose chest was narrow could easily be made fat, applies particularly to the Merino sheep, which are in general contracted in that part, and is well worth the attention of those who wish to improve this breed."—*Sir J. Sebright.*

[†] An old French writer on agricultural subjects imagines that polled cattle are degenerated. He says, "Meme en Ecosse on trouve la race tres petite, et fort souvent sans cornes."

[‡] Look at the hare and the goat, however well fed, they refuse to lay on fat.

[§] Some few have a sort of shrivelled horn, which drops off, or more commonly they rub them off in the autumn.

The influence of the male in this animal is as great as in the sheep. A few facts will show this. A friend of mine, soon after I commenced farming (thinking, no doubt, to do me a great kindness) made me a present of a sow of the wild species, in pig to a boar of the same sort. She was sent to me by sea, and during the voyage she broke out of the crib into which she had been put; and when the crew attempted to replace her, she attacked them with open mouth, and forced them to take shelter in the rigging. I put her into a high walled field, where she showed every mark of a wild animal, starting off at the least noise, and running very swiftly to some concealment. When the time of littering came near, she set to work, and carried in her mouth great quantities of withered grass and rushes, till she had a heap the size of an ordinary hay-cock. Here she had ten young ones, so concealed that no trace of them could be seen. When the heap was approached, she made a noise something like the bark of a dog, ran furiously to attack the person who had the temerity to invade her abode. In a short time the young ones made their appearance, they were all perfectly alike, being of a red or dark yellow colour, with regular black stripes, like a tiger or zebra, down the sides. As they grew old they became darker, till they resembled the sow, which was of a port-wine colour. When it became necessary to take them, the mother was secured by a noose thrown over her, and the young ones were hunted down by a number of men. When escape was impossible, they gave battle, and offered to bite very furiously.

I now put the old one into confinement, where she had a second litter to one of the pigs, which were in all points like the first. I next put her to a boar of the Duke of Bedford's improved breed. At once the litter had a totally different appearance; the pigs were all different from each other; some had a slight kind of stripe, some none, some were light, some dark. Those which had stripes when littered lost them, and grew lighter in the colour as they grew up. The leg had become shorter, as had the snout. They soon inclined to come out of the inside sty to the feeding trough, when the feeder put meat in it, and would feed while he stood by; and, lastly, they proved much better thrivers, getting very fat, which the old one and all the former pigs refused to do. I gave a neighbor a boar of the first litter which he put to several of the Duke of Bedford's sows, where the change was equally manifest; the zebra stripe, the long snout, and the length of the leg appearing in the whole of the young ones. I was now very sick of the sight of them, and sold them all off.

My stock now consisted of a cross between the Duke of Bedford's and Squire Western's improved Essex, and were as fine as any I ever saw, being as remarkable for tameness and good nature as the sort I have been speaking of were for the contrary. After breeding from these for some years, they at last got such a tendency to get fat that they were entirely lard, and almost useless from being too fat. Pork at this time had declined so much in the market, and the prices were so far from remunerating ones that I parted with my whole stock but one sow at what they would fetch, thinking the first loss the best. From this sow I had two litters (previous to reducing my stock) by the full bred boar. They were like herself, short in the snout, had very small ears, hardly any legs, and were so tame that they would eat a few oats out of the man's hand who fed them. Having now no boar of my own, I had to look out for one; and being informed that a gentleman and neighbor of mine had a pretty good one, I sent a man and cart to beg the loan of him. I chanced to be in my yard when the man returned. My surprise was great when I found he had a beast muzzled and tied down with a quantity of ropes: and, on his being turned into the sty, he proved to be a beast raving and foaming at the mouth, with long legs, a long snout, ears twice the size of the sow, and a long shaggy coat covering lank sides. In short, it looked as if my man had got a hyena out of Mr. Polito's caravan, rather than a boar from my neighbor's farm-yard; and, when put together, they by no means answered to the words of the old song—

> "Oh, sure a pair was never seen
> So justly formed to meet by nature."

The offspring of this alliance was exactly what I expected; the cross had greatly increased the size, the pigs being longer than either of the parents, while much of the boar was to be discovered in them; the snout had considerably lengthened, as had the ears and legs. The whole of my breed were pure white, with hardly any hair on them. The pigs were some black, some spotted and had a sufficient supply of bristles; and above all, they were lively, active, wild things, refusing to come near their food while any one stood by, and had lost much of the tendency to get fat.

I have thus produced facts of the influence of the male on the progeny in the horse, the cow, the sheep, and the sow, and in all I have endeavored to show to the Society, that, whether that parent be the high bred one or not—whether to improve or to deteriorate—it is the *male* which has by far the greatest influence over the offspring. I would still quote one fact more, which has come under my own eye; it is in the common fowl. In the year 1810, I procured a breed of the Malay or Chittagong fowls, and those I crossed once or twice with cocks of the same breed, got from different quarters. In spring 1824, they had been bred from cocks reared at home for three or four years, and were then all dark-coloured, without a white feather, having either black or yellow legs. Most of them resembled a partridge. At this time I learned there was in a farmer's possession a breed of fine Malays, which his brother (a surgeon on board an Indiaman) had brought home. I sent and purchased one. He was what cock-fighters termed "pied," or in other words, had numerous white feathers all over his body, with white legs. From this cock there were bred, in summer 1824, about seventy-eight chicks, of which number seventy-three were either pied or had a great deal of white on them; and a great proportion of them had white legs. Nothing but the influence of the male parents could have done this, for the hens were all gallant hens, not a white feather was to be found amongst them; nor could it have been owing to their ancestors, for they had all pedigree as long as Sir Watkin Williams Wynn.

Thus far have I stated facts which are known to myself and friends only; I would now mention some which are within the reach of all. Let us call to mind the offspring from the mare and the jackass. Is it not obvious to all the influence the male parent has on the mule? Colour, shape of head, ears, and whole body, constitution, even temper, are all derived from the male parent. I had an opportunity of observing the very same effects in the colt from a quagga and a mare, in the possession of the Earl of Morton, at Dalmahoy.—And his lordship, I believe, observed that the same mare, afterwards covered by a horse, retained in the progeny a resemblance to the quagga,* a fact of the most extraordinary nature.† I have been frequently told that a mule got by a horse, with the female ass, is a far superior animal, and retains the mane, with the ears much less, &c; but this is a fact I never could get to the bottom of. I only know it is believed by the Spaniards.‡ Nothing can be more striking than the power of the male in birds. It is well known that bird fanciers, as they are called, put a cock goldfinch to a hen canary, and that way get a strong, beautiful mule-bird, having the greater part in plumage, song, and total appearance of the goldfinch, and showing, to the most trivial observer, that the male had the greatest influence in the progeny. Every one knows that the hen of any bird will lay eggs although no male be permitted to come near her; and that those eggs are only wanting in the vital principle which the impregnation of the male conveys to them. Here, then, we see the female able to make an egg, with yolk and white, shell and every part, just as it ought to be, so that we might, at the first glance, suppose that here, at all events, the female has the greatest influence. But see the change which the male produces. Put a Bantam cock to a large-sized hen, and she will instantly lay a small egg; the chick will be short in the leg, have feathers to the foot, and put on the appearance of the cock; so that it is a frequent complaint where Bantams are kept, that they make the hens lay small eggs and spoil the breed. Reverse the case; put a large dunghill cock to Bantam hens, and instantly they will lay larger eggs, and the chicks will be good sized birds, and the Bantam will have nearly disappeared. Here, then, are a number of facts known to every one, or at least open to be known by every one, clearly proving the influence of the male in some animals; and as I hold it to be an axiom that nature never acts by contraries—never outrages the law clearly fixed in one species, by adopting the opposite course in another;—therefore, as in the case of an equilateral triangle, on the length of one side being given, we can with certainty demonstrate that of the remaining; so, having found these laws to exist in one race of animals, we are entitled to assume that every species is subjected to the self-same rules—the whole bearing in fact the same relation to each other as the radii of a circle.

Now, then, to the point of expediency. Let us suppose that I have formed an erroneous opinion, and that other essayists bring forward counterproof, to shew the power of the female. What difficulties arise in changing the whole females on an extensive farm, while with what ease a new male is procured! Sir John Sebright says, "Many females throw progeny unlike themselves, and it would be wise to try them with a male whose stock is known previous to breeding from them." How should we manage if we found it necessary from this cause to put away a set of females, which we had procured from a great distance, for the very purpose of improving our breed? If proof were required in a thing so plain to common sense, the enormous prices given for males in comparison of females, would show the advantage of getting that sex which can give the breeder a hundred of his offspring in a season in place of one. Another advantage is the letting out the males to hire for the season, a thing greatly to be wished the society would encourage, and give premiums for. The system is productive of the best consequences, a few of which it may be well to bring before the society; and be it remembered that it is only by the male, for a thousand obvious reasons, that it can be done. When a person has bred or purchased a male, he not only does not like to put him away, although he perhaps has found out that he is not well calculated, either as to cross or selection, to suit the females he has to put him to; but from the partiality which we all have for our own, it is ten to one but we think an animal, which, in truth, is of no value, to be a very fine one; and thus the breeder patters on with an inferior animal, instead of year by year selecting such a male for hire as he sees would be best suited to correct the faults of his stock. Look to the good arising in our breed of horses from this system, which in fact public stallions exemplify. Look how the districts in England where the practice of letting bulls and rams by the season exists, have far outstripped the rest of the island in the excellence of the stock which they possess; and let any one say if the benefit resulting from it is not self-evident. If such a thing were to be introduced in Scotland, and I shall hope one day to see it introduced under the patronage of the Highland Society, it ought decidedly to be in the shape of shows or competitions. Then a spirited farmer, or a few neighbors, could join and procure a fine animal at an easy rate: then the ignorant pretending judge would be told the truth by the verdict passed on his property by the public, who would not spare either his veracity or self-conceit; comparison would teach all a better taste and judgment; fine animals would be brought from England, and all parts of the country; and rewards not only of fame, but of emolument, would be conferred on the man who paid the greatest attention to his trade, and consequently brought forward the finest animals. I do not think I can better conclude than by quoting the words of Sir John Sebright, whose ideas on the subject altogether coincide with my own. "There is, perhaps," says he, "no means by which the breed of animals can be so rapidly and so effectually improved, as by its being the particular business of some breeders to provide MALE *animals* for the purpose of letting to hire. No trouble or expense will be spared by those who expect to derive profit, not from the quantity but from the quality of the animals which they breed; the competition which must always exist between breeders of this description will be a never-failing stimulus to exertion.—The common farmer, who seldom sees any stock but his own or that of his neighbors, generally concludes that his have arrived at the summit of perfection. But the breeder, who lets for hire, must frequently submit his own male animals to the inspection of the public, and to the criticism of his rivals, who will certainly not encourage any prejudices he may entertain of their superiority. Thus each, besides the improvement of his stock, will receive a fair remuneration; and every breeder have the means of selecting the male he thinks best calculated for the females he may happen to possess."

I have now, I humbly conceive, shown not only that it is the male parent which is capable of most speedily improving the breed of live stock connected with agriculture, but that *the male is the parent,* from motives of sense and sound polity, which we can alone look to for the improvement of our breed of live stock.

[*From the Journal of the American Institute*]

To the Committee on Silk, American Institute:

GENTLEMEN—The vast importance of the silk culture to our country, and the eagerness of the public to obtain information respecting it, make it the duty of every one engaged in producing a "silk crop," to furnish his quota of knowledge, that thus a mass of practical information may be collected, from which we may go forward with confidence, and gather in the rich harvest which is before us.

With these views, and in compliance with the solicitation of my fellow-citizens, I give you the result of my experience during the past summer. I would first premise, that in making a trial of the silk culture, it was my desire to adopt a mode which could be followed by our agriculturists at large, rather than to show the greatest possible quantity of silk that could be produced from a given portion of land. Such an experiment, made under peculiar advantages of soil and culture, yielding a large product, might be viewed with admiration, but the means being beyond the reach of the mass of our citizens, the same results could not be attained.

The field from which the experiment was made, was situated in East-Hartford—the soil, of a light sandy nature, of a quality termed in that quarter, good corn land. It was ploughed about the middle of May, and harrowed and furrowed in the usual manner. The roots and trees (Morus Multicaulis,) were now laid down, and covered from two to four inches, the tops having a slight upward inclination; they were placed about twelve inches apart in the row, the rows three and a half feet apart, having been previously moderately manured.

After the field was planted, a section comprising one eighth of an acre was marked off, to be subjected to a more particular experiment. It was stocked with 780 roots and trees, all of one year's growth, having had their tops partially or wholly killed by the severity of the past season. One-third were two feet high, one-third one foot, stripped of their limbs, and the remainder were roots without tops. By the first of June, the new shoots began to show themselves, and by the first of July, they numbered 4,800, and had attained the height of twelve to eighteen inches.

A family of 4,000 worms was now started, which wound up on the 23d July, having consumed 131 lbs. leaves. Three other lots, amounting in all to 28,000, were now put out at intervals of several days, in order to favor the increasing growth of the leaves. By the 10th of September, the last had finished their labors.

---

* The quagga is the species which links the zebra and the ass.

† An account of the circumstance alluded to by the author is given by the late Lord Morton, in the Phil. Trans. for 1821, p. 21.—(EDIT.)

‡ If a mule be remarked in Spain as particularly neat and handsome, the muleteer will always say, "Si, signor, caballo estavo, padre:" Yes, sir, a horse was his father.

Weight of leaves consumed in August, 701 lbs. and in September, 332 lbs.

Total weight of leaves gathered,......	1,164 lbs.
Total number of worms fed,..........	32,000
Producing nine bushels cocoons.	
Yielding (so far as reeled,) 1 lb. of silk per bushel.	
Weight of cocoons,................	95 lbs.
Waste silk and floss,................	1 lb.

Twenty-seven thousand of the worms were of the two crop kind, requiring 4,000 to make a pound of silk, and consuming 144 lbs. of leaves. The remaining 5,000 were of the long crop six weeks worms, 2,500 of which produced a pound of silk, and consumed 90 lbs. leaves. It was my intention to have fed the long crop worms entirely, as they are known to be much the most productive of any other kind, but they could not be procured.

Business now calling me away, the feeding was discontinued, and the trees were immediately removed from the ground, having attained an average height of 4½ feet, well rooted and with heavy limbs.

The produce of the one-eighth of an acre, as above, it appears is nine bushels cocoons, or nine pounds silk; being at the rate of 72 lbs. per acre, from the feeding between the first July and the 10th September. It is easy to see, that had the 1,164 lbs. leaves been fed to worms of the six weeks kind, the yield would have been 13 lbs. of silk, or nearly—and from the rapidity with which the new leaves were developing when the trees were removed, it is presumed that had they remained during September, enough more might have been added to have swelled the product, so as to have made the crop at the rate of 125 lbs. per acre.

During the period of feeding, the safety and even advantage to the tree of frequent defoliation was fully proved. The trees from which this experiment was made, were stripped of their leaves four different times, yet at no time were they inferior to others that were untouched; on the contrary, it was remarked, that where the leaves were removed, the limbs shot forth with greater vigor—care being taken to leave the tender leaves at the ends of the branches.

The very great advantage of this species of mulberry over standard trees, was manifest; while such trees are difficult of access, and from the small size of the leaves, requiring much labor to gather any quantity, it was easy for a child to take from the Morus Multicaulis 15 to 20 lbs. in an hour.

The plan of retarding the hatching of the eggs by keeping them in an ice-house, was found perfectly successful; the worms which wound the finest cocoons were thus kept back until the 3d of August.

It may be useful to new beginners to know, that the large six weeks worm, either white or sulphur coloured, is altogether preferable to the two crop; for, not only are they more productive of silk, but from their superior length of thread, the reeler is able to produce silk of better quality, and with less labor.

The convenience of a shrub tree, where the farmer wishes to change his crop, may be seen from the fact, that with the use of a plough, the trees on this section of land, 4,800 in number, were turned out of the ground in 30 minutes. An hour more was sufficient to cart them from the field.

Every one who takes up the culture of silk, is surprised at the ease and certainty with which it is produced; and of this experiment it may be observed, that none of the persons who took care of the trees, gathered the leaves, or fed the worms, had ever seen a a tree or a silk worm before.

I am not acquainted with the comparative merits of the Morus Multicaulis, and other kinds of the mulberry; but large as has been the estimate of some cultivators, of the produce and value of the former, I believe its astonishing power of reproducing foliage, its tenacity of life, and the great ease with which it is multiplied, have never been overrated. A friend informs me, that a field of roots, deprived of their tops last fall, remained in the ground during winter, and that from the new shoots, which started as early as any other vegetation, he was able to feed from one to two months earlier than from others planted the following May.—From these collected facts, we may form an idea of the quantity of leaves, and the consequent weight of silk that may be obtained from the Morus Multicaulis, when it shall have attained greater age, even in this latitude.

I am not able to name the cost of raising silk; but an intelligent culturist of my acquaintance, from a proof of three successive years, rates it at $2 per lb. exclusive of the cost of trees and the tillage; respecting the latter, I am of opinion the labor bestowed on a field of mulberry, need not be more than on a field of Indian corn.

It appears, therefore, that nearly all the labor of raising silk, viz: plucking the leaves, feeding the worms, and reeling it into sowings, may be performed by the females of a family, and thus the product be considered a clear gain, like that of any other collateral branch of farming. The growing of silk needs but to be looked into, to be appreciated; and if 100 lbs. can be produced the first year of planting, worth $5 the pound in raw silk, or $9 when in sewings, what other crop, it may be asked, can be named coming near it for profit?

I will only add, gentlemen, that it is cheering to see the interest the American Institute has taken in this all-important subject, and to express the hope, that the coming exhibition, from our silk growers, and the increased patronage of the Institute, may give to it a fresh interest. Yours respectfully, J. DANFORTH.

Hartford, Sept. 19th, 1838.

New Publication.

We have received from the respected author, W. H. Ellsworth, of Lafayette, Indiana, a pamphlet of some 200 pages, entitled, "The Valley of the Upper Wabash, Indiana, with hints on its agricultural advantages;" illustrated with a map, engravings of labor saving machines, &c. Mr Ellsworth is a gentleman every way competent to the task he has undertaken, and his book has conferred a signal favor on the northern part of the flourishing state of Indiana. Hitherto the northern part of that state has been a terra incognita, and while the stream of emigration has flowed along its borders to Michigan and Chicago, few comparatively, owing to difficulty of communication, have found their way into that fertile section of the west, the Wabash Valley.—That difficulty is now overcome, or will be so in the course of the next year, by the completion of the Erie and Wabash canal, which commences near Toledo, at the mouth of the Maumee, and terminates at Lafayette, the head of steamboat navigation on the Wabash.

Mr. Ellsworth has drawn his picture of that section of the great west, in strong and bright colours, but perhaps not stronger than facts would fully justify. It is a country in which corn, the sugar beet, and the mulberry, can be cultivated with as great success as in any part of the United States, and its general agricultural advantages, can scarcely be exceeded, when fertility of soil and ease of cultivation are considered. The excellent report made by Mr. Ruggles to our legislature at its last session, has furnished Mr. Ellsworth with valuable matter for his appendix, and he has also furnished extracts from the letters of other gentlemen, on points that had not fallen under his personal notice. Mr. Ellsworth gives tables and statements showing conclusively that the great thoroughfare to the west, both for travel and trade, lies through New-York; but at the same time demonstrates that this great state must not relax its exertions in the cause of internal improvement, if she would maintain her present high vantage ground. We may refer to Mr. Ellsworth's book hereafter, in the mean time we cordially recommend it to the notice of emigrants to the Mississippi Valley.—*Genesee Farmer.*

An Address

Delivered before the Rockbridge Agricultural Society, at its Annual Fair, Oct 11th, 1838, *by* George D. Armstrong, A. M. *Professor of Natural Philosophy and Chemistry, in Washington College, Lexington, Va.*

Communicated for publication in the Farmers' Register.

Gentlemen of the Agricultural Society—The subject which I have selected as affording a theme suitable for the present occasion, is—the value of natural science to the farmer. The practical rules of agriculture, and the best methods of cultivating the great staples of our country, would have afforded a more appropriate subject, had I felt myself competent to the task. But with my imperfect acquaintance with those matters, any attempt to communicate information to the members of this society, must have proved worse than useless. The importance of agriculture to the prosperity of our country, and the honor which is due to the independent American farmer, would have afforded a theme in the highest degree grateful to my feelings; but its discussion could not have been of any real value. In such a country, and in such a state of society as ours, where the farming part of the community are acknowledged to be "the bone and sinew of our strength," that class upon whom more than upon all others, our national prosperity depends, the poor tribute of my praise, could neither make them more honored in fact, nor to feel themselves so. Precluded as I am from the discussion of either of these subjects, which would have been most appropriate to the occasion, I will be pardoned for selecting a theme, which in other circumstances I should have left untouched.

The system of agriculture pursued in this section of country has, within a few years, undergone a change for the better. Whilst a country is new, presenting a deep rich soil, which has never been vexed for the support of man, it makes comparatively little difference in what manner it is tilled. All that is necessary is, to bury the seed in the earth, and in due time to gather home the golden harvest. But if a careless system of agriculture be pursued for a time, the soil becomes gradually exhausted. Instead of gathering an abundant crop almost without labor, the farmer is compelled "to eat his bread in the sweat of his brow." From year to year, whilst the amount of his necessary labor is increased, the return for those labors becomes more and more scanty; until at length a point is reached at which the only alternative left him, is to change his system of cultivation, to emigrate, or to starve. There are portions of our southern country which have nearly reached this point—and the tide of emigration is fast sweeping off their old population to the new countries of the west and southwest, those lands of promise. Accustomed for many years to a certain routine of farming operations, they either would not, or they knew not how to change it for a better. The valley of Virginia, possessing as it does a soil which it is difficult if not impossible entirely to exhaust, has never become impoverished to such an extent; yet, even from the valley of Virginia, not a few have sought a home in the distant forests of the west. Far be it from me to call in question, either the policy of such a movement, or the patriotism of those who have made it; doubtless they have found a richer soil; and having carried our free institutions with them, wherever they have gone, they still possess all that which most endears his native state to the bosom of a Virginian. But those who remain behind, have a work to perform. By long cultivation, the soil has become so much exhausted, that it is necessary for our systems of cultivation to be improved, if we wish still to see "smiling plenty reign in the home of our childhood." Instead of making it the one absorbing question, how can I get the largest return from my lands this year? our farmers must inquire, how can I get the largest return in a series of years? how can I permanently improve my lands? This I suppose every one is ready to admit; but then the question arises, how is this change for the better to be effected? in what way are our lands to be improved? in what respects ought our systems of cultivation to be changed? It is not difficult to mention some way in which lands may be improved, and some particulars in which our systems of cultivation might be changed for the better; but to give a correct and full answer to these questions, to state in what manner lands may be permanently improved to the best advantage, and how our systems of cultivation may be changed, so that a given portion of land shall yield the largest return, with most certainty, least labor, least detriment to the soil, is a task which it is impossible to perform at the present day; and we can hope to do it only after long-continued and careful study of the subject.

It is at this point that natural science may be advantageously introduced to assist us in our labors. I know that in time past, while men have acknowledged the importance of applying science to the arts, and in fact to almost every thing else, they have doubted the value of its application to agriculture. Is this a reasonable doubt? What do we mean by natural science? As I understand it, we mean nothing more nor less, than our knowledge of nature arranged and generalized. Our knowledge on all subjects is, in the first instance, a knowledge of individual facts. After a stock of facts has accumulated, we perceive that many of them are of the same character; these we class together, and include them under a general statement. Again, we observe that some of these facts bear to others the relation of cause to effect, and we arrange them in accordance with this observation. This once accomplished, our knowledge has become science. By this process, the form, and not the nature of our knowledge is changed. Scientific principles are nothing more than human knowledge packed up in a portable form. Founded as they are upon our observation of nature, their application to the affairs of life, is one of the very best methods of testing their truth.

To the arts, and to almost every other business of life, natural science has been applied with the happiest result; and is there any thing which forbids the hope of its being applied to agriculture with equal success?—There are departments of physical science, which apply as naturally and as directly to the business of the farmer, as mechanical or chemical philosophy do to the business of the artizan. Such are mineralogy, geology, and vegetable physiology. One great object of mineralogy and geology is to enable us to determine the character of soils, to ascertain the elements which enter into their composition, and the proportions in which they severally enter. No one has ever doubted that the difference between a fertile and barren soil, lies in a difference in their composition. There are some combinations of the elements of soil, which seem particularly adapted to the growth of plants, whilst there are others which will scarcely support a scanty vegetation. A piece of land may be rendered barren, either by the absence of some one or more of the elements of good soil, or by the presence of some noxious principle. If the former is the case, it is to the interest of the possessor to supply the deficiency; if the latter, to remove the noxious principle. But how shall he set about this work, unless he know whether it is the absence or the presence of an element which renders his land barren, and also what that element is? Lime and vegetable matter are our two most common manures. To make it a general question, as has sometimes been done, whether lime or vegetable matter is the best manure for land, is very much like making it a general question, whether fire or water is the best agent for doing work. Unless the nature of the work to be done is specified, it is impossible to answer the question. For smelting iron, fire is the best, and water is good for nothing; for removing a stain from linen, water is the best, and fire is good for nothing. So it is with respect to manuring; it is necessary that we should know the nature of the soil, before we can determine the proper method of improving it. It is (as I have already mentioned,) one great object of mineralogy and geology to enable us to ascertain the nature of soils; the former, teaching us to distinguish them by their external characters, the latter by their position.

Let this suffice for mineralogy and geology—I wish to direct your attention mainly to vegetable physiology; a department of natural science, which has hitherto been little valued and little understood; and yet one which applies more directly to agriculture than any other. Under the title of vegetable physiology, is comprehended whatever is known respecting the structure of plants, and the history of vegetable life; embracing our knowledge of the nature of the organs of plants, the offices these organs perform, the manner in which they perform these offices, and the changes which they naturally undergo, or which they may be made to undergo by the art of man. Its object is to lay open the machinery of vegetable life, and to explain the manner in which that machinery operates. In order the more distinctly to illustrate the application of such knowledge to practical agriculture, I will select that which concerns one subject, viz: the circulation of the sap. We all know that plants are nourished by their sap, just as animals are by the blood which circulates through their veins.

If we inquire for the point at which the sap enters a plant, we find it to be the root, but not all parts of the root alike. There is a peculiar class of organs whose office it is to absorb nourishment from the soil; and these are situated along the fibres or smaller subdivisions of the root; of course it is at these points and no others that the sap enters. Let us see if we can make any practical application of this knowledge. If we wish by manuring, to assist the growth of a tree, we should place the manure at some distance from the point at which the trunk enters the ground, so that it may lie as nearly as possible over the fibres of the root. If we wish to plant a vine so as to twine around a tree and be supported by it, we should plant it very near to the point at which that tree enters the ground, rather than at the distance of several feet from it; because in this way the two will interfere least with each other's growth. If we wish to transplant a tree, we should be more careful about the extremities, than about the main divisions of the root. If the root have several branches, it is better to cut off all those branches excepting one, and retain that with all its subdivisions perfect, than to cut off the ends of all the branches, as is the common practice.

Again—if we trace the course of the sap during the different seasons of the year, we find that in such trees as the oak, the hickory and the chestnut, it circulates principally in the sapwood during the spring and summer, but during the autumn and winter it retires to the heart-wood, and not to the root, as is generally supposed. In order to satisfy ourselves of this, nothing more is necessary than to take a part of the body of a small tree cut in the spring, and of another cut in the winter, and lay them on the fire. The sap will be seen to exude in the first from near the surface; in the second from the heart. Let us see if we can make any practical application of this knowledge. It is generally acknowledged that, that most destructive disease in timber called the dry-rot arises from the presence of the sap. It is generally the heart-wood which we use for timber, whilst the sap-wood is considered of little value. If then the situation of the sap at different seasons is such as I have just mentioned, in order to get our timber free from the sap, we should cut it in the summer and not in the winter. The course thus indicated is, I know, in direct opposition to the common practice of men. As this is a matter of some practical importance, permit me to cite one fact in confirmation of the rule which I have laid down. The fact is mentioned in connexion with many others of a similar character, in a communication from a very intelligent ship-carpenter to one of our scientific periodicals. "In accordance with the common practice of ship-carpenters, I was in the habit of cutting my timber in the winter.—During the summer of 1810, when engaged in framing a vesssel, I found I had no piece which was suitable for a certain place in the frame. It was necessary that the work should go on, and as the only alternative left me, I sent immediately to the woods and had a suitable stick cut; this I framed in with the others. After several years the vessel was sent back to me to be repaired.—On examining her side-timbers, I found them all more or less affected with the rot, excepting this one, whilst it was perfectly sound."

Again; if we inquire into the nature of the sap, we find that as it enters the vegetable system, it consists mainly of water holding carbonic acid gas in solution Water has the power of absorbing large quantities of certain gases, whenever it is brought in contact with them. Strange as it may seem to those who have never thought much on the subject, water is porous, and absorbs these gases just as a sponge absorbs water.—The great object of manuring, in most instances, is to supply carbonic acid gas to the growing plant. A large portion of this gas is liberated from vegetable matter during its decay; and hence the value of such matter as manure. The gas furnished by the manure, must be absorbed by the water, as it sinks down into the ground. Of course, the water should meet the manure before reaching the roots, and not after it has passed beyond them. This would suggest that the manure could be placed to the best advantage upon the surface, because then the water must pass through it before meeting with any of the roots. But, then, there is a difficulty arising from another source. The valuable material furnished by the manure, is furnished in the form of a gas. If the manure is placed upon the surface, it soon dries, and whilst in that state, as the gas is liberated, no water being present to absorb it, it is soon dissipated in the atmosphere. The two facts taken in connexion, suggest that the manure should be placed as near the surface as is consistent with its being kept in a moist state, and in every instance, above the roots of the plant which it is intended to benefit. Where manure is spread upon the ground in the fall to benefit a winter crop, it should be placed very near to, if not upon the surface; where it is spread in the spring or early part of summer it should be always covered with earth.

Our knowledge of the nature of sap, enables us to explain the manner in which clover improves land.—Had we no experience on the subject, it would seem, to say the least, improbable that any crop could improve land. We would naturally suppose that plants were nourished by the ground itself—that they fed upon the soil. If such be the case, when a crop is ploughed under and decays, it can give nothing but what it has first taken; and how then can it improve land?—Yet we find that growing clover upon land, and then ploughing it under and suffering it to decay, is one of the very best methods of improving land. Bearing in mind the nature of the food of plants, this admits of a simple explanation. We will suppose that clover is sown upon a perfectly barren spot. The atmosphere which is above this spot, contains a portion of carbonic acid gas, for all atmospheric air contains a greater or less portion of it. A rain comes; as the rain falls, it absorbs a portion of this gas, and in this condition enters the ground. No sooner does it come in contact, with the seed in the first instance and with the root afterwards, than it is absorbed and its materials used for increasing the size of the vegetable structure. When the portion of air above the spot, has in this way been exhausted of carbonic acid, a supply is obtained from the neighboring portions, in consequence of that strong tendency which gases manifest, to intermix and diffuse themselves throughout each other. This process is repeated again and again, and thus the clover increases in size. Perhaps some one may ask, from whence is this gas obtained in the first place? From many sources, but principally from decaying vegetables, such as are found in the woods and along the fence sides. The quantity of the several elements which enter into the composition of our globe, is fixed; it is impossible for man either to increase or diminish this quantity, and it is equally impossible for him to convert one of these elements into another. All he can do is to make an economical use of that which already exists, to gather up those portions which subserve no valuable ends, and apply them to use. This is what the farmer does in sowing his land with clover. He impresses the very wind into his service, for every wind that sweeps over a field of clover, laden as that wind is with the materials of vegetable structures, is made to contribute to its growth. After a large portion of vegetable matter has, in this way, been collected upon the once barren spot, it is ploughed under and secured for future use.

Again; in absorbing nourishment from the earth, the roots of a plant do not seem to exercise any choice; but drink up every thing, presented to them in a sufficiently fluid state. This we learn from actual experiment. Almost any substance which is soluble in water, may be made to enter vegetable systems. After a heterogeneous mass is thus taken up by a plant, such portions as are suited to its nourishment are retained, whilst such as are not suited, are returned to the roots, and by them again deposited in the soil. From observation, we learn that the matter thus rejected, is thrown back in such a state as to be not only unsuitable to the nourishment of the plant (rejecting it) but positively deleterious. It has also been ascertained, that the substances rejected by different plants differ from each other; and this to such an extent that the matter rejected by one plant, is well adapted to the nourishment of another. With a knowledge of these facts, we can assign the reason, why it is not a good plan to sow the same crop upon the same piece of land for several years in succession. It will not do to say (as is often done) that a second crop of wheat will not grow as well upon the same spot, as the first, because that spot has been so much exhausted by the first. This is, it is true, one reason; but if it be the only reason, or even the principal reason, why is it that a crop of corn succeeds so well? The failure in the second crop of wheat, arises not so much from the exhaustion of the soil, as from that soil's containing a portion of matter positively deleterious to the growth of wheat, and which was deposited by the first crop. At the same time this matter is not injurious to the growth of corn, and hence the crop of corn is almost as good as it would have been, had wheat never been sown upon the land. If we could ascertain the precise character of the matter which is retained, and of that which is rejected, by each of the several crops commonly cultivated, it would be an easy matter to determine the best order in which crops can succeed each other. Perhaps too, if this subject was better understood, we should find that the way in which some manures benefit crops, is not by supplying nutritious matter to them, but by removing this deleterious matter from their roots. If this matter possess the character of an acid, as it is more than probable it does in some cases, lime would act in this way. Being a salefiable base, it would unite with the acid and neutralize its properties.

I might go on and multiply instances such as these, did the occasion call for it: but as my object is, not to give a lecture on vegetable physiology; but by illustrating its application to agriculture, to show its importance to the farmer, these will suffice. Perhaps some one may ask, if scientific principles are nothing more than facts, arranged and generalized, why is it, that knowledge in this form, is more valuable, than in the form of unconnected observations; the form in which this knowledge is at first obtained?

There are several reasons. Knowledge in the form of science is more easily retained, and is more perfectly at the command of the possessor, than it can possibly be, in the form of unconnected observations. I doubt not that the experience of every one here will confirm the statement, that it is easier to remember fifty effects, when we can trace them to one common cause, than it is to remember five, when we can trace them to no cause. A knowledge of the cause of any number of effects, serves as a band, by which they are bound in one common bundle, and thus secured from being scattered and lost. It is one of the characteristics of science, that the relation between cause and effect is distinctly traced out.

Another reason why it is desirable to have our knowledge in the form of science is, that in this form it will serve to direct us in our course of experiment and observation. Such is the constitution of nature, so intimately are the various parts of creation interwoven, that a cause generally gives rise to several effects.—When we have traced an observed effect back to its cause, we can generally infer other effects, which will spring from the same cause; and these often of a character entirely different from the one first observed. To illustrate my meaning by an instance. In attempting to sink a pump to an uncommon depth, it was found that the water could not be raised by it, to a height greater than thirty-two feet. The cause of the rise of the water was ascertained to be the weight of the atmosphere. The reason why the water would not rise to a heighth greater than 32 feet, was that the weight of a column of our atmosphere was only equal to that of a column of water of the same diameter, and 32 feet high. It was at once inferred, that as the weight of the atmosphere was fixed, it must sustain columns of different liquids at heights, inversely proportioned to their specific gravities. And again; that as we rose from the level of the sea, leaving as we must, a part of this atmosphere behind us, the height at which a column of any liquid would be sustained, must diminish in proportion to our rise. Thus by tracing the refusal of a pump to act in certain circumstances, to its cause; we ascertain, in the first place, a method of determining the specific gravity of liquids; and in the second place, a method of determining the height of mountains. The effects by which we determine these things, spring from the same cause as the refusal of a pump to act, and yet they are of such a character that we never should have dreamed that there was any connexion between them, had we not traced them to their common cause; and more than this, we should probably have remained long in ignorance of the two last mentioned effects, had we not traced the first to its cause. Thus it is, that throwing knowledge into the form of science, is like putting it out at compound interest.

Another reason why it is important to have our knowledge in the form of science, is that in this form it will greatly assist us in observing facts, and collecting information. When the attention has been directed to any particular subject, facts connected with that subject are observed and remembered, which, in other circumstances, although they might have passed before the eye, would have made no impression on the mind.—Let a farmer and an architect travel together, through the same country, you will find that although they must have seen the same things, yet they have brought home with them entirely different kinds of information. The farmer can give you an account of the soil, the condition of the crops, the methods of cultivation, &c.; whilst he can tell you little or nothing of the structure of the buildings which he has passed. The architect, on the other hand, can give you a minute description of every principal building on the way, whilst he can tell you little or nothing respecting the crops. The difference arises entirely from the fact, that these two men have had their attention previously directed to different subjects. By throwing our knowledge into the form of scientific principles, we get a number of subjects worthy of attention, distinctly out before the mind, and each of them will be a nucleus around which knowledge will naturally collect.

Such are some of the arguments, which urge a study of natural science upon the farmer. The want of success, which has in many instances attended the efforts to apply science to agriculture, may be brought forward as an objection, by some. To such I would answer, this want of success is to be attributed, in part to the present imperfection of those sciences which most naturally apply to agriculture; and in part also, to the visionary character of many of those who have hitherto made the attempt. If you will consult the history of the application of science to those of the arts to which it has been most successfully applied, you will find that this has been a misfortune which has happened to them all, in their infancy. Visionary men being the lightest part of society, seem always to rise to the top; and rising science, like the rising sun, is forced to shed its first rays upon those barren spots, where it is impossible that any thing should grow. Let it rise higher, and pour its flood of light upon the rich valleys below, and if it cause not these to spring with life and verdure, then may you fairly call its claim in question. If the attempt has failed hitherto, in consequence of having been made by visionary men, the greater is the necessity that sober, substantial, practical men should now take the matter in hand.

Much has already been done in Virginia for the advancement of the interests of agriculture. A geological survey of the state is now in progress. An able periodical, devoted exclusively to diffusing information respecting the best methods of cultivating and improving land, has been established, and thus far well sustained. And last, though not least, societies such as that whose anniversary we to-day celebrate, have been established in many parts of the state. Thus far it is well. There is yet another, and, as it appears to me, an important step to be taken. The nature of that step and my reasons for believing it important, I have presented before you. "I have spoken as unto wise men, judge ye what I say."

Every inducement is held out to the farmer of the valley to improve his land and his system of cultivation.

Who that looks upon the inexhaustible water-power of our state, and at her vast mineral resources; the iron and the coal, which the hand of a bounteous Creator has so lavishly bestowed upon her, can doubt, that she is yet to become one of the principal manufacturing states of the union. Thus will she possess within herself a market for all that her farmers can produce by the most skilful cultivation. The James River improvement will soon open a grand highway, from the valley to the very centre of this market. Our climate is well adapted to the growth of every species of grain; our soil is already good, and susceptible of the highest degree of improvement. What then is there to forbid the hope, that the valley of Virginia may yet rival in fertility the fairest portions of the west? Let our farmers but improve the advantages which they have; let them engage in earnest in the work, and this hope must soon become a reality.

The traveller as he rests for a moment on the top of yonder mountains, will cast his eye over a broad land of golden harvest. As he descends and mingles amongst us he will receive the hospitality of an intelligent, a blest, a happy people. The inhabitant of the valley has already much to rejoice in. He trembles not before the chill wind of the north, neither is he stricken down under the oppressive heat of the south; surrounded by a scenery so grand and beautiful, that no part of the country can boast of a superior; possessed of a mount-girt home, such as has always been the strong hold of the freeman, let him but add to these, that fertility which he can bestow upon the soil, and with an honest pride may he exclaim, my own, my native valley, is the fairest spot on which the sun shines.

Science of Gardening—CONTINUED.

[*From the Alphabet of Gardening.*]

SCIENTIFIC PRINCIPLES OF DIGGING AND RAKING.

It must be evident that a soil having a hard crust on the surface, will neither admit water and air, nor allow the water and air already below the surface to escape and circulate freely—circumstances indispensable to the healthy growth of plants. It is with such views, as well as to render it more easy for plants to extend their roots in search of food, that digging is performed. The extraordinary effect thereby produced is strikingly shown by the experiments of Mr. Curwen, who found that the quantity of water which rose in the form of vapour from an undug surface was exceedingly small, whereas from an acre well labored there were no less than 950 pints carried off into the air in one hour.

So great a loss of water might, however, be in many gardens injurious, by rendering the soil too dry, and, in that case, it might be useful to employ the roller when the plants would admit of this, or place fern leaves, or the like, so as to prevent too rapid a loss of water.

Raking very smooth will have a similar effect, by diminishing the extent of the surface exposed; and hence where there is too much moisture, smooth raking must be bad practice, and rough digging or trenching the best for sending off the superabundant moisture into the air.

When a soil is what is popularly termed *sour*, that is, too moist in consequence of water lodging in it without free circulation, it is often advantageous to turn it over by repeated rough digging, going as deep as it may be advisable, according to the quality of the under soil. This indeed is always of importance in regulating the operation of digging; for otherwise, if the upper soil is rich in the materials of the food of plants, it may be turned too deep for the roots to feed upon it, while if the under soil is the richer in the food of plants, it will be useful to bring it up from some depth to the surface. The testing of the soil to be dug, at various depths, will therefore be always important before proceeding. Dr. Home, as we have seen, found barren under soil or *till* usually impregnated with iron.

ACTION OF FROST ON SOILS.

Very erroneous notions, it would appear, are commonly held respecting the action of frost upon soils, which it may be well to examine here. Even scientific men have concluded, that frost, by crystallizing the water retained in clay soils, tends to loosen it, by separating the particles; all which seems very plausible, but plain facts and experience demolish the theory. Instead of being expanded, and the particles separated from the swelling of the ice accordingly, it is found, that wet clay squeezes out the water to the surface, while the particles of the clay become more tenacious, solid, and close; the process being similar to what takes place upon freezing salt dissolved in water, in which case, all the salt is forced either into the centre, or into separate solid masses surrounded by ice. This view is farther proved by the well known fact of newly transplanted strawberries, and the smaller pebbles on a garden walk being loosened and thrown out by the frost squeezing the soil more firmly around their lower bevelled parts, from the action of which they escape gradually upwards; whereas the larger pebbles on a gravel walk will, in slight frosts, be seen to sink a little, from the pressure caused by the frost not being below them. It will hence be injudicious to rough dig a stiff or watery clay soil with the view of mellowing it by frost, and still more to expose clay intended for composts to freezing. An ample dressing of fresh farm-yard dung, containing much straw, or of wood or coal-ashes, will answer much better with such a soil, from the straw facilitating the introduction of air, and the circulation of water, and the ashes separating the particles of clay. Dressing clay with sand, at least in any small quantity, which has been recommended, will only tend to stiffen the clay, as must be evident from the processes of brick and porcelain making, in which sand is indispensable to mix with clay to harden the goods. In order to be beneficial, the sand must be in proportion of at least one half, or more, to the clay.

I may mention here, also, that the common notion of frost tending to kill insects, is far from correct.

LEVELLING AND DRAINING.

One of the most important things effected by digging is the levelling of the surface in cases where the soil is very light, and liable to become parched for want of a sufficient supply of moisture; for the sun, having less effect upon a level surface, because the rays of light run in straight lines from the sun, will not carry off so much water as from a slope. By the same principle, when a soil is too wet and cold, the forming of the garden into a slope, if the expense can be afforded, will be of great advantage.

Although draining is rather extensively practised, I question whether its principles are sufficiently understood; for it is obvious, from what I have already detailed, that this will not depend altogether on getting rid of superfluous water, but upon the circulation thereof which is effected, and also upon the circulation of air that must be consequent upon all under ground drains formed with potsherds, broken slates, or brush-wood. I even question whether such drains might not, on this account, be of advantage in gardens, in which the soil was dry enough not to require any lodged water to be carried off.

SCIENTIFIC PRINCIPLES OF SEED SOWING.

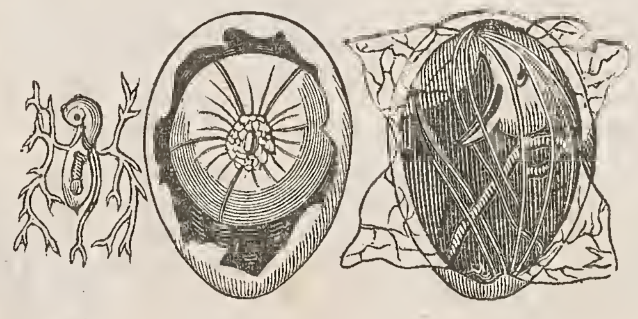
I have already hinted, that the food of young plants, when they first germinate, or begin to *braird*, as it is provincially termed, is very different from that of full grown ones; for, instead of taking up the ordinary food, they depend in a great measure upon the materials stored up in the seed, in much the same way as the chick, before it breaks out from the egg, depends in a great measure upon the food stored up there. I have used the qualifying phrase, "in a great measure," both in the case of the young plant, and of the chick, though it may appear, at first view, to some that the chick enclosed in the shell has no means of obtaining any food not included in this form without,—but two other principles are indispensable; I refer to heat and air.

Heat, if it do not form a portion of the food of the chick, and of the plant, is indispenable, either for exciting and stirring up into activity the vessels which carry the nutrient materials to the parts where they are wanted, or, as all fluidity depends on heat, for rendering the food sufficiently liquid to pass into and along these vessels.

Such is the theory, and it accords with the established facts, that a chick cannot be hatched in a heat less than one hundred and four degrees of Fahrenheit, while seeds require heat from forty to eighty degrees, above or below which they will not germinate well. As we have seen, however, that buds once roused into growth, will go on to grow even when cold recurs, so seeds, after germinating in artificial heat, may have the plants thus produced planted with success in the open air.

[Fig. No. 70.]

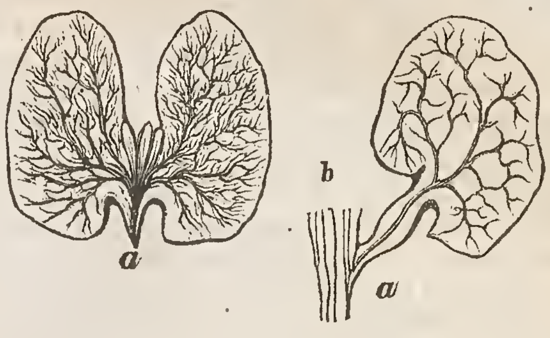
Eggs during the process of hatching, broken open to show the vessels supplying nutriment to the chick, which is shown separate from the egg on the left.



Air is supplied to the chick in the egg through the minute pores, or holes, in the shell, and probably to the seed of the plant in a similar way, though this is a point not well known. It is the oxygen of the air which is the indispenable material, both to the chick and the plant, for when confined in carbonic acid gas, or in azote or hydrogen, they both die. Too much oxygen, however, like too much heat, will excite growth too rapidly, and disease, and at last death, will be the consequence.

[Fig. No. 71.]

The nutrient vessels in the seed lobes of a germinating bean, magnified.



EFFECTS OF WATER AND STEEPING.

So far the chick and the seed have a close resemblance; but water, so indispensable to a grown fowl, would, in the smallest quantity, kill the chick in the egg, while it is equally necessary for the evolution of the plant from the seed, as it is to the full grown plant. Seeds that appear to have germinated without water, must have derived moisture from the air.

The principal effect of the water, when introduced within the shell of the seed, appears to be that of dissolving or, at least rendering more liquid, the portion of it whose use is similar to the contents of a bird's egg. The starch also, which is generally, if not always, in this portion of the seed, is converted into sugar, a process that can be imitated artificially.—Along with this some mucilaginous matters are observed rendering the food of the embryo plant not much unlike, in chemical qualities, to animal milk. The contents of the seed, thus changed into a sort of milky pulp by the addition of water, swell by degrees, and the first point of the future root having formed, breaks through the shell in a downward direction (*a*) and about the same time, the first point of the future stem comes forth in an upward direction (*b*,) as may be seen in the figures.

It will be an obvious inference respecting water, that, like the oxygen and the heat, if it be in too great quantity it will render the contents of the seed too thin, and weak, and will also increase their quantity so much that the vessels of the embryo plant will be gorged, and disease or death will follow. When the quantity of water again is not enough to produce this effect, still it may be in such large proportions as to push the growth too rapidly for the health of the plants, which will in that case be too pale on appearing above ground. Hence the importance is clear, of sowing in dry rather than moist weather.

Hence also the practical error, at least in most instances, of steeping seeds; which is chiefly useful in separating the infertile seeds that may swim on the water. All steeps which contain any thing but water and oxygen gas, are unnatural, and must be injurious; such, for instance, as urine, or drainings of dunghills loaded with humic acid, which embryo plants cannot feed upon, any more than a new born infant could drink strong ale or wine with impunity. Some strong infants might survive taking such drink, as some strong seeds may survive the steeps, but these survivals would not justify the practice. Steeps are recommended with a view to destroy the eggs of insects, but I am not acquainted with any destructive garden insect that lays its eggs upon seeds, and I am quite positive, supposing them to exist, that no steep would kill such eggs which would not at the same time kill or greatly injure the seed.

I am not aware of the effect of light upon the hatching of the eggs of birds, though with respect to the eggs of many insects, light certainly does not prevent them from being fertile. On seeds light acts so powerfully in retarding their germination, that though they have a due degree of heat and a due supply of oxygen and water, they will not grow, at least healthily, unless in the dark. The reason is that light causes the oxygen which is indispensable for their growth, to be carried off, and fixes in them the carbonic acid gas which is yet as improper food for the embryo plant as beef would be to a new born infant; whereas in the dark, the carbonic acid gas escapes into the soil, while the oxygen is taken up into the embryo plant.

Hence the importance of putting seeds deep enough into the soil to exclude the light, taking care at the same time not to put them too deep to be out of the influence of fresh circulating air. From half an inch or less to an inch, is about the average depth for garden seeds.

TIME OF GERMINATING.

Some seeds, such as those of the coffee plant, require to be sown immediately on being gathered, otherwise the nutrient matters contained in the shell become too hard to be dissolved in water. Others, as holly berries, require to be kept for about twelve months to mellow. It is said, and I believe in many instances proved, that seeds, such as those of the balsam, if kept for several years, are more apt to produce plants with double flowers, in consequence, it would appear of their nutrient matter being more condensed.

The period between sowing and germinating is very different according to species. Mustard, for example, will germinate in one day, or less if stimulated with chlorine; cress in two days; turnips in three days, lettuce in four days; parsley in about six weeks or two months; the peach in one year; and the rose and filbert in two years.

It has been proved by experiment that seeds gathered before they are quite ripe, germinate sooner than very ripe ones, obviously because the nutrient matter is less hard and more easily diluted with water; and on the same principle, I have proved by experiment, that potatoes, when saved green for planting and kept in bran, will come several weeks earlier than others. It would be worth trying the roots of the dahlia and marvel of Peru on the same principle. Though seeds, when gathered before they are quite ripe, germinate sooner, it does not follow that they will produce the best plants.

SCIENTIFIC PRINCIPLES OF TRANSPLANTING.

The removing of growing plants from one part of the garden to another is done for various reasons, and the science of transplanting will consequently depend on the intention of the gardener in the operation. The principal facts to be recollected are, that every plant takes its food by the tips of the root fibres, and that the sap thence carried up into the leaves has much of its water and oxygen carried off by exposure to light, particularly to sunshine. It follows that if part or all of the tips of the root fibres be broken off or bruised, the plant will be kept hungry or starved, just as an animal would be with its mouth much injured or blocked up; while if a plant in such a state is placed in the sunshine, the water and oxygen carried off thereby will very soon cause it to flag, wither, and die.

TRANSPORTING.

If the gardener's object then be simply to move plants from one place to another without affecting their growth in any way, it will be important to preserve every root fibre entire; and even, when this can be done, to take it up with part of the soil in which it has been growing, or with a large ball of earth, as it is termed. When this cannot be done, the root fibres ought to be placed in their new station as nearly as possible in the manner they were at first, and hence dibbling, where the soil is at all stiff, will be bad practice, from its being certain to confine and crush the root fibres within the walls of the dibbled hole.

It is partly upon the principles here laid down, that Sir Henry Steuart, of Allanton, has succeeded in removing the largest trees without heading down the branches, as was wont to be practised.

If it be found impossible to preserve the root fibres from injury, or to replant them exactly as they were, then, in order to diminish the loss of water and oxygen, the plants ought to be shaded from the light, or if that cannot be done, they ought to have a suitable proportion of their leaves or branches cut off. De Candolle says this practice was wont to be so universal on the continent, that the gardener's maxim was, "if you plant your own father, you must cut off his head." Sir Henry Steuart has proved the bad science of such universal barbarity.

Without taking up the soil in an undisturbed state, it is difficult to transport, uninjured, plants having few root fibres and large leaves, such as the poppy, because the few spongelets of the fibres which supply the sap are apt to be obstructed in a new soil even when free from injury.

PRICKING OUT SEEDLINGS.

The object in what is termed pricking out seedlings, is different from simple transportation. In the case of early lettuce, for example, or early annuals, such as balsams and coreopses,* it arises from the necessity of sowing the seed under the influence of artificial heat, in order to get plants of some size sooner than they could be had by sowing in the open air.

The lettuces cannot be improved and are almost certain to be injured by the operation, in consequence of their small number of root fibres (not quite so few as in the poppy) and the largeness of their leaves. Accordingly, lettuces, when pricked out under the most favorable circumstances of moist cloudy weather, always flag more or less, and hence the leaves are apt to be checked in their growth so as to be less juicy, their juiciness depending on the most rapid and unchecked growth that can be effected. Rich soil, however, and plentiful watering, may overcome the check in the growth from pricking out.

In the case of the balsams and the coreopses, the check in growth from pricking out is advantageous, because the leaf pulp becoming much thickened by the great loss of water and oxygen, when it returns to the stem and to the life knot or crown of the root, it lays the basis of fresh branches terminating in flower buds. Whereas were a seedling plant to remain unmoved in a rich soil well watered, it would probably send up more sap than the light could readily deprive of its water and oxygen, and thence would push out new leaves to carry off the superabundance, while there would be no pulp formed thick enough and containing enough of carbon to produce flowers.

It is important not to plant the roots too deep, so as to be out of the reach of air, or too shallow to expose them to drought. By a natural proces an ash will send its roots across a deep ditch, keeping always under the soil about six or ten inches and rising again on the other side. In a dry season, the roots of trees will dip down in search of moisture into a bad under soil.

For the same reason, either kidney or broad beans if taken up and transplanted when only a few inches high, will have their growth checked, and will flower and fruit sooner, though they will not grow so tall, as those which have not been transplanted. It is on the same principles advantageous to transplant brocoli, Brussels sprouts and cauliflower, which will make them head more readily, though care must be taken that the growth is not so much checked as to render the heads small and their stalks tough. Trees are, in their youngest state, frequently transplanted by nurserymen to increase their root fibres.

It may with this view also be advisable, in some instances to trim off some of the root fibres to diminish the supply of sap, and cause new root fibres to grow; a thing which ought never to be done where luxuriance of leaves is an object, and hence the old practice of trimming both the root fibres and the branches or leaves at the same time, is in the most cases highly absurd.

SCIENTIFIC PRINCIPLES OF STRIKING.

By certain experiments, not by any means praiseworthy, yet, beyond all question, correct, it has been proved that, if the head of a snail, or of an earth worm, be cut off, the body will not only live for a considerable time, but a new head will be reproduced, with a mouth capable of taking food. By similar experiments it has been found that the legs of spiders and the feet of frogs, when cut off, are reproduced.

Upon a similar principle, when the roots of certain plants which are to them what the head is to animals, are cut off, new roots may, under peculiar circumstances, be reproduced. The chief condition required for the reproduction of such roots, is the preservation of their life till the roots have time to form, and various expedients are resorted to with this view, as well as for the quick production of the roots.

CHINESE MODE OF STRIKING.

The simplest mode of striking is that practised by the Chinese, and which I have tried successfully with the lilac. Lord Macartney was surprised to find in the Emperor of China's hall of audience a number of dwarf pines, oak, and orange trees bearing fruit, in frames filled with earth, and placed on tables. These are produced by selecting a fruit-bearing bough, with a good branchy head, and taking off from the stem a ring of bark about an inch in length. Around this is placed a ball of rich earth, tied on with bass or coarse cloth, and the whole is kept moist by means of a vessel of water hung over it with a very small hole, or a thread to convey the water drop by drop. The descending pulp being stopped short in its passage downwards towards the root, first forms root buds, which soon send out roots into the moist earth, and when these are deemed strong enough to feed the plant, the branch is cut off a little below, and the tree in minature is ready for planting in a pot.

The process has been varied by having garden pots made so as to enclose the ring branch, and in this way dwarf fruit-trees are often formed on the continent, where they are much prized.

STRIKING BY LAYERS.

The common mode of striking by layers proceeds on the same principle. Some plants may be said to propagate themselves by layers, such as the strawberry, which sends out runners that take root, and the ends of the common bramble sometimes take root in a similar way. A willow or a privet branch also, if accidentally bent down into the ground, will send out roots, and become a new tree, if separated from the parent.

But in most instances, it is requisite so to interrupt the downward flow of the pulp, as to cause it to form root fibres, and hence, in practice, the branch intended as a layer, is slit, tongued, or cut half through in a direction sloping upwards, or it is ringed, as in the Chinese mode, or it is pierced in several directions by a brad-awl, or it is wired or twisted; all of which operations have the same design of checking the descent of the pulp, while the sap going up in the more central parts is not interrupted, and consequently the layered branch grows as well as, if not better than, if it had not been so treated. The soil ought not to be too damp, otherwise the cut part may canker.

Towards the end of the autumn, layered plants are, for the most part, sufficiently furnished with new roots to feed them without farther dependence on the parent plant; but they are in general still weaker than seedlings, and require to be not only watered, but the more tender sorts not exposed to too bright sunshine.

STRIKING BY SLIPS, OR CUTTINGS.

In the preceding modes of striking, the layer, being partly in communication with the parent plant, is in no danger of perishing for want of food; but, in the case of cuttings, the circumstances are much the same as in the experiments alluded to, made upon the snails and earth worms, inasmuch as they are deprived of their natural feeding organs, their root fibres. In the first instance, therefore, a cutting like the headless snail and earth worm, must live entirely on the nutrient materials it already possesses, which are, as we have seen, partly laid up in the cells of the stem, but more particularly in the buds. Hence it becomes important to have a bud, or buds, on every cutting intended to be struck; but leaves, or at least many leaves, are disadvantageous, as tending to exhaust life, by giving off too much water and oxygen. In the case of evergreens, however, in which the action of the leaves is so slow as not to produce exhaustion, they must be left on, to assist in maturing the pulp for the new roots, but no such leaves must remain below the surface of the soil, lest canker ensue.

The end of a cutting, to be planted in the soil, ought to contain a heel of older wood than the bole, or stem, and be cut very smooth, in order to prevent water from stagnating in any crevice or bruise, and thus tending to rot the part. The heel of older wood is to prevent too much water being taken up by the more active and more open vessels of the bole, which would render the whole dropsical and sickly.

For the same reason, rich earth, very retentive of water, is bad for most cuttings; and species difficult to strike require to be planted either in pure sand, or in a soil containing a large proportion of sand to drain off all superfluous water which ought to be supplied in small quantities, but frequently, so as to keep it in constant circulation. Hence, orange-trees can only be struck by a drain of broken potsherds in the bottom of the striking pots. This is one of the true scientific principles of striking cuttings.

Another is founded on the effects of light upon leaves, or buds, which being furnished with only a scanty supply of food, cannot stand much loss of water and oxygen; and hence they are covered with a bell glass, both to modify the intensity of the light, (some light is indispensable,) and to render the included air moist, from the water given off in the form of vapor. Some fresh air, however, is as necessary as some light, in order to produce a healthy leaf pulp, and hence, the bell glasses must not be kept air tight.

When bell glasses are not used, it is found that cuttings succeed best in a border with a northern aspect, protected from the wind; or, if otherwise situated, they require to be screened from the force of the noonday sun.

The same principles of supplying regularly a moderate portion of water, so as not to cause dropsy by overgorging, and of sheltering from too much dry air, and bright sunshine, so as not to cause exhaustion, regulates the striking of buds, or *eyes*, as they are termed, which always require a leaf attached, and even of leaves themselves, such as those of the cacti.

SCIENTIFIC PRINCIPLES OF GRAFTING.

When the finger is cut with a knife, the blood vessels soon after contract their cut extremities into an opening so narrow, that the thicker and red-coloured part of the blood cannot pass, and the bleeding therefore ceases. But even then there oozes out the thinner watery part of the blood, consisting chiefly of matter the same or similar to the white of an egg, which being thus separated from the rest of the blood, thickens by the heat of the body, as the white of an egg does by boiling. If the lips of the finger-cut accordingly be kept close together by sticking-plaster, they will become united by means of this natural glue, as it may be termed, in little more than a day. Upon the same principle, when I was a student of medicine, I once succeeded, as others have done, in managing to unite the whole tip-joint of a finger which a boy had chopped off by machinery; and experiments have been successful in causing the spur of a cock to unite and to grow upon his comb.

It is upon similar principles that the science of grafting is founded; for if a young branch, like the boy's finger, be chopped off by a clean cut, and the cut extremities immediately joined, the decending pulp will thicken like the watery part of the blood, and while it remains soft, the sap from the cut ends of the sap vessels will force its way through to their continuation above in the cut slip, which, if the process be successfully managed, will grow as well, or nearly, as if had never been cut.

If, again instead of applying the same cut slip to the part it was cut from, a slip from another tree be applied, as if I had applied to the boy's finger the tip of another boy's, chopped off by the same accident, there seems no good reason to doubt that a similar healthy joining might, by care, be effected. In the case of animals, indeed, such joinings are rare, because rarely tried; but in garden plants they are exceedingly common; for the purpose of continuing esteemed varieties of fruits and flowers, accidentally produced by cultivation, as well as for forwarding the fruiting of young trees—since seedlings require years to arrive at a bearing state.

---

* It is correct to say "one Coreopsis" and "two Coreopses."

On examining the joining of a graft about a fortnight after it has been made, I have found, as in a healing finger-cut, a number of small roundish grains, in form of a thin layer, produced from the thickening of the pulp, and destined to form the hard substance which in general projects a little externally, and the scar differs in appearance from the other parts of the bark. It is, however, only in the space between the pulp-wood and the bark that the uniting substance is formed, and therefore it is evident the slip to be grafted must have this part applied to the same part of the stock, and, if these differ in thickness, at least on one side.

BINDING OF THE GRAFT.

When the joining has been made by cutting and properly fitting the bark of the slip to the bark of the stock at least on one side thereof, it must be bound so as to prevent this junction from being deranged. This is usually done with a ball of three parts of clay free from stones, well worked with one part of fresh horse-droppings and a little finely chopped straw, the whole about an inch thick, and two inches or more in length, being tied with a ribband of bass.

The principle upon which this is done, is to prevent the oxygen of the atmosphere from getting to the fluid pulp at the joining, where it would unite with the carbon and form carbonic acid gas, and thereby rob the pulp of its solidity. The exclusion of light is necessary on the same account, for, as in the case of a finger-cut, the oxygen would unite with the carbon and prevent the thickening of the matter from the blood. On the same account, moisture, by supplying oxygen, would be injurious; and dryness might act both by exhausting the pulp and by causing the edges of the bark to shrivel and gape, which would facilitate the entrance of the air with its oxygen.

It must be obvious from this simple principle, (never, that I am aware of, before stated with reference to grafting,) that no composition, whatever may be said of its peculiar power of healing, can act in any other way than this; any more than the farrago of plasters and salves for healing flesh wounds and cuts, which are only good in so far as they keep the lips of the wound together, and exclude oxygen and light.

[The following communication was received after our paper for February, was at press. We therefore give it in our supplement, and we do it with pleasure, as the readiest means of correcting the mistatement which it imputes to our correspondent.—*Cond. Cult.*]

Hon. Jesse Buel—Dear Sir—The undersigned members of the executive committee of the American Society for the Diffusion of Useful Knowledge, beg leave to state to the readers of the Cultivator, that the charges by an anonymous correspondent, in the January number of that paper, against the society, and those charged with the management of its affairs, must have arisen from a want of knowledge of the operations of the institution, and are without any foundation whatever.

The committee will make a more particular reply in the March number of the Cultivator. The number of gentlemen acting on the committee, and the intervals of their meetings, make it impracticable to forward an answer in season for the next number.

Passed in Committee, January 18, 1839.

Cha's Sam'l Stewart,	James Brown,
Geo. F. Allen,	Thomas Cock.
John T. Gilchrist.	A. P. Halsey.
Cornelius Baker.	J. Proudfit.
John Torrey.	John A. Vaughan.
Gorham D. Abbott.	

[The following, like the preceding communication, came too late for its proper place in the Cultivator. We give it without comment—leaving the reader to form his own conclusions of the matters in controversy, and to impute blame, if any is called for, wherever he may think it ought to attach. We only say, we believe we have much yet to learn, in regard to the relative merits of the different species and varieties of the mulberry.—*Cond. Cult.*

J. Buel Esq.—In the January number of the Cultivator, is a long article purporting to be editorial, containing reflections upon Samuel Whitmarsh and D. Stebbins, saying however: "We do not mean to charge these gentlemen with wanton deception, for we have a high opinion of their standing, yet there is something so contrary to received opinions, that we cannot pass them as current truths, without asking for some explanation:" and demurring at the assertion of Mr. W. "that the Alpine is the kind universally used in France and Italy," and for authority to the contrary, the declarations of Gen. Tallmadge, and others are offered to show, that the black and white mulberry are most used. But by late intelligence, however, from Europe, the Alpine mulberry is recognized, as well as the morus multicaulis, for American market. Yet it is not of a fig's consequence to us, what kinds of mulberry are known or used in Europe, provided we have the same, or others, congenial to our climate, and producing the best of foliage in equal abundance and quality for growing silk.

Mr. W. was sent out by the Northampton Silk Company, (as understood) to visit the most noted silk districts, to inform himself as fully as practicable, on the whole subject of growing and manufacturing silk, which of course would involve inquiry for the best kind of mulberry for our use.

In the next place, the motives of Dr. Stebbins are called in question, for advertising the *Manilla multicaulis*, the *Canton*, the *Alpine*, the *Asiatic*, the Smyrna, the Brussa, Dandolo and others; about which, the editor says: "Now we protest against the fabrication of new names for old things—whether it be from ignorance—for novelty, or to subserve the interest of the trade"—rather crude suggestions however. Although it has been sometimes said, that we are to judge others by ourselves. He considers the *Alpine*, *Asiatic and Smyrna*, to be absolutely of new coinage, "that this unnecessary multiplication of names, tends to mystify the business—to deceive the public, and retard a useful branch of national industry, and believes that *all* named in the Doctor's advertisement, are merely varieties of the white mulberry, &c."

Thus, the editor substantially confirms, what is stated in the advertisement about the morus multicaulis, Brussa and Dandolo mulberry. And here it may be observed, that by no fair construction of language, does it any where appear that there is any "*insinuation*" made, that among the trees named, or alluded to in the advertisement, that any of them are "unfit for the entire subsistence of the silk-worm, and the production of excellent silk." The suggestion appears wholly gratuitous on the part of the editor.

I am sorry that the words, "neither *ingenuous* or *true*," have been so applied by him, nor can see any particular necessity or use of the following sentence, unless it be for the purpose of personal abuse: "We have no objection that Doctor S. should puff his own wares, or his own kind of trees.—but we do object to his doing it to the prejudice of others and of truth." This same sentence of the judge, without trial by jury, appears to be rather arbitary, for only saying: "the Brussa and Dandolo *appear* to be selected white mulberry"—while the judge may say with impunity, and without being charged of "doing it to the prejudice of others and of truth"—for he asserts that he "believes that *all* which are named in the advertisement, are merely varieties of the white mulberry."

Others have advertised more kinds of mulberries than was contained in the advertisement, and never a complaint.

Nurserymen advertise a great variety of apples, peaches, plums, pears, &c. One list enumerates 317 different kind of pears—228 of apples—154 of peaches—66 of plums—68 of cherries—all of excellent quality, and probably if asked the reason—would say, to *distinguish one from the other*, called good, better and best, and each bearing a different name.

Doctor S. had the pleasure of eating some delicious fruit, from the garden of the judge, which were called by different names, "although of the same family," and had no idea of accusing him of "the fabrication of new names for old things," or that the names were of "new coinage."

If the advertisement had been published with the criticisms, the public would have seen that the *Manilla multicaulis*, the *Canton* and *Alpine*, were so called, to designate the places of origin—the same also might be said of the others.

And now disclaiming any pretence of puffing my own trees to the prejudice of others and of truth, I would venture to ask, if it might not be gratifying to many of your readers, to see the advertisement published? and let them judge of its mystification: I have the pleasure to state, that all the names given in the advertisement, have been, and are, recognized by numerous orders from the empire state—from the remote south and west—from the east and north—where the *Canton*, Asiatic and Alpine, in particular, have become favorites, for cultivation and for making silk. No fear therefore, need be entertained by either of us, that the public will be deceived, or a useful branch of national industry retarded. Such, however, is the opinion of your respondent, with sentiments of due respect.

DANIEL STEBBINS.

Northampton, January 21, 1839.

Young Men's Department.

Chemical Catechism—Chapter VII.

[*From Parkes's Chemical Catechism.*]

OF ACIDS.

What is an acid?[*]

Most of the acids are substances which produce that sensation on the tongue which we call *sour;* but some substances are classed with the acids which have not this characteristic—though they possess some of the other properties of acids.

What are the properties of acids?

Acids change the blue, green, and purple juices of vegetables to red; and combine with alkalies, earths, or metallic oxides, so as to form those compounds called *salts.*

What is the origin of acids?

Most of the acids owe their origin to the combination of certain substances with oxygen,[†] which has been called the acidifying principle.

How is it known that oxygen imparts acidity?

This is built upon analogy; for it is found that most of the acids contain oxygen, and that they lose their acidity exactly in proportion to the quantity of oxygen which is taken from them.[‡]

Are there any other means of ascertaining this?

Yes: some acids may be decomposed, and deprived of their oxygen, and others may be formed by a direct combination of oxygen with certain radicals.

Do the same radicals always combine with an equal portion of oxygen?

No: some of these acidifiable radicals combine with different proportions of oxygen, and consequently produce different states of acidity.[§]

How is this difference distinguished?

When two acids have the same radical, but contain different quantities of oxygen, they are distinguished by their termination. The name of that which contains most oxygen ends in IC, the others in OUS.—Thus we say *sulphuric* acid, and *sulphurous* acid; *phosphoric* acid, *phosphorous* acid.

What substances are capable of being acidified by oxygen?

The mineral, the vegetable, and the animal kingdoms, all furnish bases or radicals, which become acid by their union with oxygen.[‖]

Do all the acids owe their acidity to the presence of oxygen?

The greater number of the acids are evidently indebted to oxygen for their acidity, but there are substances that possess acid properties which contain no oxygen. Until lately, there were also three acids whose composition was unknown.

How are the acids classed by chemists?

The acids were formerly divided into three classes, viz. the mineral, the vegetable, and the animal acids; but the more useful and scientific way of dividing the acids is into two classes only.

How are the acids now divided?[¶]

The undecomposable acid, and those which are formed with two principles, are comprised in the first class; while those acids which are formed with more than two principles compose the second class.

---

[*] The acids differ from each other in their appearance and properties as much as any class of bodies we are acquainted with: it is therefore difficult to give a definition of an acid.—In general they are liquids, but some of them take a solid, and others a gaseous form: some are mild, others corrosive; some are pungent and volatile, others are fixed and inodorous.

[†] The substances which are combined with oxygen to form acids are (in all the decomposable acids) *combustible* substances. Indeed several of the acids are the *product* of combustion:—witness the sulphuric, the phosphoric, &c. Five of the metals, and the other simple combustibles, hydrogen not excepted, are all convertible into acids.

[‡] Many of the acids may be decomposed, and deprived of their oxygen, by combustible bodies. Any combustible body, that has a greater affinity for oxygen than oxygen has for the radical of the acid, will decompose that acid. Charcoal, when made red hot, will in this way decompose sulphuric acid.

[§] The first portion of oxygen converts some bodies into oxides, as is the case with carbon, forming carbonic oxide; and sulphur, forming oxide of sulphur: the second into that class of acids of which the specific names drawn from their particular bases terminate in *ous*, as the sulphurous acid: the third degree of oxygenizement changes some of these into that division of acids which are distinguished by the termination in *ic*, as the sulphuric acid, &c. In like manner we have oxide of phosphorous, phosphorous acid and phosphoric acid.

[‖] The mineral acids are generally formed with a peculiar base and oxygen; the vegetable acids, with carbon, hydrogen, and oxygen; while the animal acids are composed of the same substances united with nitrogen.

Some of the mineral acids are decomposable, as already mentioned, by charcoal heated to redness. Some of the vegetable acids are also decomposed, and reduced into water and carbonic acid, by leaving them in an exposed situation to the action of their own principles: others may be changed into different acids, by imparting or abstracting a portion of oxygen.

[¶] Those acids of the first class, which are formed with two principles only, are composed of oxygen and some other substances which is called their radical. The acids of the second class are composed chiefly of oxygen, hydrogen, and carbon; though some of them contain a portion of nitrogen, as mentioned in a former note.

Can you enumerate the acids of the first class?

The sulphuric and sulphurous acids; the muriatic and oxygenized muriatic acids; the nitric, the carbonic, the phosphoric and phosphorous, the fluoric, the boracic, the arsenic and ersenous, the tungstic, the molybdic and molybdous, the telluric and the chromic acids.

Enumerate the acids of the second class?

The acetic, the oxalic, the tartaric, the citric, the malic, the lactic, the gallic, the mucous, the benzoic, the succinic, the camphoric, the suberic, the laccic, the prussic, the sebacic, the uric, the amniotic, and the fluoboric acids.

What is the SULPHURIC *acid?*

The sulphuric acid is a combination of sulphur and oxygen. It is commonly called oil of vitroil.

How is the sulphuric acid obtained?

Sulphuric acid is procured by burning sulphur, in contact with oxygen; by which process the sulphur combines with the oxygen, and becomes acidified.

If sulphuric acid is nothing more than sulphur and oxygen, what is it that occasions its fluidity?

Sulphuric acid, at the instant of its formation, is in a gaseous state; therefore the manufacturers find it necessary to condense the gas by means of water.—Hence the sulphuric aid of commerce is always in a fluid state.

What are the properties of sulphuric acid?*

The sulphuric is a very ponderous, corrosive acid, destitute of colour and smell, and has a very strong acid taste. It has a great attraction for water,† and, when combined with the alkalies, the earths, or the metallic oxides, forms with them those salts called *sulphates*.

What is the SULPHUROUS *acid?*

The sulphurous acid, like the sulphuric, is a combination of sulphur and oxygen, but with less oxygen, or, we may say with more sulphur, than the latter.

What are the properties of sulphurous acid?

Sulphurous acid, in the gaseous state, is invisible, like air, but of a strong suffocating smell.‡ It is readily absorbed by water, and then forms liquid sulphurous acid. It is capable of uniting with various bases, and forms the salts called *sulphites*.

What is the MURIATIC *acid?*

The muriatic is a peculiar acid obtained from sea-salt. Until lately, the radical, or base of this acid, was entirely unknown.

What method is made use of to collect and preserve the muriatic acid?

Muriatic acid is distilled from sea-salt by means of sulphuric acid, and collected in appropriate receivers, where it is condensed in water, for which it has a very powerful affinity.

What are the properties of muriatic acid?

This acid, in the gaseous state, is invisible, like air; and has a pungent suffocating smell. With water it forms the liquid muriatic acid, which preserves the smell of the gas, and gives out white fumes when exposed to the atmosphere. This acid is much employed in the arts, and in chemical laboratories.—With various bases it forms the salts called *muriates*.

What is the OXYMURIATIC *acid?*

It is now a prevailing opinion, that the oxymuriatic acid, or chlorine, as it is usually called, is a simple substance, It is known in the gaseous state, and in combination with water: but in the latter form it is more commonly used in the arts.

What are the properties of oxymuriatic acid?

The oxymuriatic acid gas is so suffocating, that it cannot be breathed without great injury; yet it will support combustion. This gas discharges vegetable colours; it burns all the metals,§ and is the only acid that will dissolve gold and platina:|| with various alkaline and earthy basis it forms salts called hyperoxymuriates.

What other compounds may be formed by means of chlorine, or oxymuriatic acid?

Chlorine will combine with oxygen, with hydrogen, and with nitrogen; also with carburetted hydrogen, and with the carbonic oxide; some of which combinations possess very curious properties as may be seen by reference to the notes.

Those you have now mentioned are all gaseous substances: does chlorine form any other combinations?

By peculiar management chlorine may likewise be combined with sulphur, with phosphorous, and with the metals, including also the metals of the earths and alkalies.

What effect has chlorine upon charcoal?

Chlorine has no action whatever upon charcoal, even though the charcoal be intensely hot when plunged into it. Some intelligent chemists consider this fact to be a decisive proof that chlorine contains no oxygen.

What is NITRIC *acid?*

Nitric acid is one of the constituent parts of nitre or saltpetre. It is a compound of oxygen and nitrogen, in the proportion of about 26 parts by weight of nitrogen, to 74 of oxygen.*

How is nitric acid obtained?

Nitric acid is obtained by distilling two parts of nitre and one part of sulphuric acid in a glass retort, and collecting the fluid in proper receivers.† This acid, which at first contains nitrous gas, and is thereby made of a deep red colour, is in a great measure deprived of it, and rendered transparent and colourless, by the application of heat in a subsequent process.

What are the properties of nitric acid?

Pure nitric acid is clear and colourless, like water; its smell is pungent, its taste exceedingly acid, and its action on animal substances very corrosive. It has the property of permanently staining the skin yellow. It has a great affinity for water; is capable of oxidizing most of the metals, and with various bases forms the salts called *nitrates*.

What constitutes the acid of commerce, called NITROUS *acid?*

Nitrous acid, improperly so called, is in fact nitric acid impregnanted with variable portions of nitrous acid gas.

What are the properties of nitrous acid?

Nitrous acid is somewhat similar to *nitric* acid in its properties; but its colour varies according to the proportions of nitrous acid gas which it has absorbed, and the water that it contains.‡

What is CARBONIC *acid?*

Carbonic acid is a combination of carbon and oxygen. It was formerly called fixed air, on account of its being so intimately combined in chalk, limestone,§ magnesia, &c.

What are the properties of carbonic acid?

Carbonic acid is invisible when in the state of gas, and unfit for combustion, or respiration. Water, by pressure may be made to absorb three times its bulk of this gas; by which it acquires an agreeable acidulous taste. Carbonic acid in the proportion in which it exists in atmospheric air is favourable to the growth of vegetables, but in a large proportion is highly injurious. This acid enters into combination with the alkalies, with earths, and metallic oxides; and forms with them those salts called *carbonates*.

What is PHOSPHORIC *acid?*

Phosphoric acid is a compound of oxygen and a peculiar substance called phosphorus.

How is phosphoric acid procured?

Formerly phosphoric acid was procured only by burning phosphorus in oxygen gas; but, since it is known that this acid is a component part of animal bones,|| we now procure it at a much cheaper rate from that source.

What are the properties of phosphoric acid?

Phosphoric acid is very soluble in water: the solution is colourless; it has a strong acid taste:* by evaporation the solution becomes very dense and of an oily consistence. This acid may by evaporated to dryness, and even submitted to a white heat, without suffering any change, or being volatilized. It forms by its union with earthy, alkaline, and metallic bases, that variety of salts which we call *phosphates*, and occurs in nature combined with lime, oxide of lead, and other bases.

What is the PHOSPHOROUS *acid?*

This acid contains a smaller proportion of oxygen than the phosphoric acid. It is procured by the *slow* combustion of phosphorus; for when phosphorus is heated it burns *rapidly*, and the product is phosphoric acid.

What are the properties of phosphorous acid?

Phosphorous acid is a dense, viscid liquid, with an acid taste, and emits the smell of garlic when heated. This, like the phosphoric acid, may be decomposed by charcoal, but cannot be obtained in a concrete state. It has not yet been applied to any use. The salts formed with it are called *phosphites*.

What is FLUORIC *acid?*

The fluoric is an acid of a very peculiar nature, found in the fluor spar,† which is a natural production, composed of fluoric acid and lime. This acid is found also nearly in the same proportion in the *cryolite*, a rare mineral brought from West Greenland. The topaz likewise contains fluoric acid, though in a less proportion.

What are the properties of fluoric acid?

In the state of gas it is invisible like air. Water rapidly absorbs it, and forms liquid fluoric acid. It has an acid taste, and the peculiar property of corroding silica. With the alkalies and earths it forms salts called *fluates*. Though it has been decomposed, the nature of its radical is not yet known.

What is the use of fluoric acid?

Fluoric acid has been used for etching upon glass; also in various cases for destroying the polish upon glass, so as to render it nearly opake. It appears that it was employed for the first named purpose so early as in the seventeenth century.

What is the ACETIC *acid?*

Acetic acid is principally obtained from saccharine liquors which have undergone the vinous formentation.

What are the properties of acetic acid?

Acetic acid, as it is usually prepared, is a pleasant yellow liquor, well known. When distilled it is as colourless as water, and of an agreeable odour. In both states it is known in commerce by the name of vinegar.

How is the concentrated acetic acid, or radical vinegar as it is sometimes called prepared?

Concentrated *acetic* acid is obtained from acetate of copper, acetate of soda, or acetate of potash, by decomposing either of them by means of sulphuric acid, and then distilling the product.

What are the properties of acetic acid in this state of concentration?

Acetic acid thus prepared is very pungent, acrid

---

* When sulphur is combined with a smaller portion of oxygen, it forms a volatile acid of a penetrating smell called *sulphurous* acid; a larger portion of oxygen gives what we call *sulphuric* acid, which on the contrary is very ponderous, and destitute of smell. These acids are constituted in the following manner:—*Sulphurous* acid consists of 100 parts of sulphur and 100 of oxygen; while *sulphuric* acid is composed of 100 parts of sulphur and 150 parts of oxygen.

† Sulphuric acid and water combine so intimately that the compound gives out a large portion of caloric. Four pounds of this acid mixed with one pound of water will raise the thermometer to 300° of Fahrenheit.

‡ Sulphurous acid gas is used by manufacturers in bleaching straw and silk. A slow combustion sulphur is promoted in a close chamber, and the goods are exposed to the gas as it is produced. Thus, silks, which are dyed by archil of a dark lilac, are brought to a beautiful flesh-colour by the fumes of this gas. Flesh-coloured silk stockings are also colored in this way.

§ Metals beaten into thin leaves, or reeuced to powder, inflame when thrown into a vessel filled with this gas, provided the temperature be not lower than about 70°, and present a kind of shower of fire.

|| Mr. Humbolt has found that seeds which do not commonly germinate in our climates, or in our hothouses, and which, of course, we cannot raise for our gardens or hope to naturalize in our fields, become capable of germinating when immersed, for some days, in weak solution of oxymuriatic acid. This interesting discovery has been turned to advantage in some botanic gardens.

* It is curious that the gases which compose atmosphereic air, so necessary to our existence, should, in different proportions, produce also one of the most corrosive acids.

21 parts by weight of oxygen,
mixed with } form atmospheric air
79 parts of nitrogen
———
100

74 parts of oxygen,
with } when chemically combined and condensed by water, form nitric acid, or aquafortis.
26 parts of nitrogen,
———
100

Surely none but Deity could have conceived an idea of the production of such *different* susbtances from the *same* principles!

† The manufactories of this acid are commonly called AQUAFORTIS WORKS. The acid is drawn of different strengths, according to the purposes for which it is designed. It is used in dying, in refining gold, in medicine, and in a great variety of manufactories.

‡ The changes which take place on the addition of water to strong nitrous acid exhibit very curious phenomena. Different portions change its colour to a blue, a geeen, a yellow, &c. while the vapours which rise from it preserve their original flame-coloured red.

§ Carbonic acid is composed of about 28 parts carbon and 72 oxygen.

|| When animal bones are divested of their oil and jelly, the earth which remains is chiefly lime, united with phosphoric acid, and this phosphate of lime is often employed for the preparation of the medicinal salt called phosphate of soda. But Mons. Chaptal jun. son of the Count Chaptal, employs bones in Paris, as I am informed, in a very different manner. Having a large establishment for the preparation of soda, in which process a larger quantity of muriatic acid is afforded than can be consumed in the ordinary way, he employs persons to collect bones from all parts of the city, and digests them in this spare muriatic acid. The acid disselves the phosphate of lime and leaves the gelatine. The latter is made into soup, and sold in every district in Paris.

It is worthy of notice, that phosphate of lime is found in abundance also in milk. This seems to indicate, as Fourcroy beautifully remarks, "that Nature thought fit to place in the first nourishment of animals a quantity of osseous matter, with a view to the necessary celerity of the formation and growth of the bones in the earliest stage of their lives."—This fact is probably unknown to some who study natural history, and is one of the numerous instances of the beneficence of the Creator, exemplified by the science of chemistry. The more we know of the minutiæ of matter, and of the laws by which it is governed, the greater occasion shall we have to admire the excellence of contrivance and the benevolence of intention of the Omnipotent Artificer. Let the advocates for chance consider the aforesaid fact, and say, if they can, that phosphate of lime is found in animal milk, in consequence of *fatality*, and that it occurs by *accident* where it performs so important an office in the animal economy. It is also a remarkable fact, that the nearer the female approaches to the period of parturition the more is the milk charged with this calcareous phosphate; and that it is not till the digestive organs of the infant are sufficiently strengthened to answer the purposes and the work of animalization, that this earthy salt disappears from the milk of the mother.

* Pure phosphoric acid obtained, without the addition of water, by burning phosphorus in oxygen gas, has the form of white, snowy, light flocks, of a very strong acid taste. By exposure to the air it attracts humidity, and becomes a *fluid* acid. One hundred parts of dry phosphoric acid consist of about 46½ phosphorus and 53½ oxygen.

† Fluor spar is found in many parts of Europe, particularly in Derbyshire. It is employed in the manufacture of ornamental vases, &c. It is constituted of about 67 per cent. of lime and 33 of fluoric acid.

and volatile, and corrodes animal substances. With various bases it forms the salts called *acetates.*

What is OXALIC *acid?*

The oxalic is a peculiar acid found in the juice of sorrel, in combination with potash. Several substances also, and particularly sugar, contain the bases of this acid in a convenient form for conversion into oxalic acid by combining it with oxygen; and hence it has also been called the acid of sugar. It crystallizes in four-sided prisms, has a very acid taste, and is soluble in water. It is composed of oxygen, hydrogen, and carbon.

What are the uses of oxalic acid?

Oxalic acid is of service in detaching the presence of lime in solution. It is also become an article of great consumption with the calico-printers, both in the state of crystallized oxalic acid, and in that of superoxalate of potash. In combination with earths, alkalies, and metallic oxides, it forms the salts called *oxalates.*

What is TARTARIC *acid?*

Tartaric acid is a particular acid found in the tartar of commerce.* It is capable of crystallization, and easily soluble in water. It is used by calico-printers to discharge false prints. The salts formed with it are called *tartrates.*

What is CITRIC *acid?*

Citric acid is found in the juice of lemons and several other fruits. It crystallizes in beautiful rhomboidal prisms, is extremely acid to the taste, and very soluble in water. It is used in various ways for domestic purposes, for medicine,† and in the arts. The salts formed with it are called *citrates.*

What is MALIC *acid?*

Malic acid is obtained from the juice of apples, in which it exists ready formed.‡ It is a very acid, reddish-coloured liquid, composed, like the other vegetable acids, of oxygen, hydrogen, and carbon. It is incapable of crystallization, and has not yet been brought into any use except as a chemical test. Its salts are called *malates.*

What is LACTIC *acid?*

Lactic acid is prepared by a peculiar process from milk after the curd has been separated. It is an acid of a yellow colour, incapable of crystallization, and has not hitherto come into use. The salts formed with it are called *lactates.* The earthy and alkaline lactates are all deliquescent salts.

What is GALLIC *acid?*

Gallic acid is found in the galls of commerce, and in most astringent vegetable substances. It is obtained in thin transparent plates, and in minute needle-shaped crystals, of an acid austere taste. It has the property of precipitating iron, from its solution in acids, of a black colour. Its salts are called *gallates.*

What is PRUSSIC *acid?*

The prussic is a peculiar acid, composed of hydrogen, nitrogen, and carbon. It is a colourless liquid, like water, has a sweet taste and does not alter the colour of vegetable blues. It is of great use to chemists for detecting metals in solution. It is prepared from blood and other animal substances; and when united with iron, forms that beautiful colouring substance called prussian blue.

What is URIC *acid?*

The uric or lithic acid is found in human urine.—Some of the human calculi are composed entirely of this acid. When pure it has neither taste nor smell, but it reddens vegetable blues, and combines with alkalies and earth. It is a composition of carbon, nitrogen, hydrogen, and oxygen.

How many different distinct acids are there?

The number of the acids that are well known amounts to about thirty; besides which, a variety of substances have been announced, as new acids, by some of the foreign chemists, that require to be further examined before they be finally admitted into this class of bodies.

What are the USES *of these various acids?*

The uses§ of the acids are so many and important that it is impossible to enumerate them. They are indispensable to various arts* and manufacturers;† they are employed for culinary purposes,‡ and for medicine:§ they act an important part in the great elaboratory of nature,—they produce that numerous class of bodies called salts, and form a great proportion of many of the rocky and mountainous districts of the globe we inhabit.

Do you recollect any instances of acids entering into the composition of rocks and mountains?

The vast masses of limestone, chalk, and marble, which are found in every part of the world, are combinations of lime and carbonic acid:‖ the mountains of gypsum in the vicinity of Paris and elsewhere are combinations of lime and the sulphuric acid.¶ The fluor spar of Derbyshire is composed of lime and the fluoric acid;** and there are masses of common salt, both in the eastern and western hemisphere, which contain such immense quantities of muriatic acid†† as would render every attempt to calculate the amount abortive.

Are you sure that the acids which Nature has employed in the formation of mountains, are of the same kind as those which come under our common notice and observation?

Yes: any of these native mineral substances may be decomposed, and their acids exhibited in a separate state for experiment or use.‡‡

Do you know of any other natural productions which contain considerable quantities of any of the acids you have described?

The large masses of celestine§§ and of ponderous spar‖‖ in different parts of the earth contain an incalculable quantity of the sulphuric acid; the cryolite¶¶ of Greenland is a compound of alumina, soda, and the fluoric acid; and several of the valuable minerals, together with some of the precious stones, are combinations of the different earths with the chromic or the phosphoric acids; not to mention the annual changes which the vegetable kingdom undergoes by the formation and subsequent decomposition of the vegetable acids.

You speak of the formation of acids:—Are bodies of this class formed and decomposed by the common operations of nature?

Many of these bodies are the result of, and formed by the action of vegetable life, such as the malic and citric acids; some are formed principally by chemical changes effected on dead vegetable matter, as for instance the acetic; and others, as the sulphuric, occur in the mineral kingdom, and are also formed artificially, in great abundance.

Objects, Advantages and Pleasures of Science.

[*From the American Library of Useful Knowledge*]

* * * Reflect how many parts of the reading, even of persons ignorant of all sciences, refer to matters wholly unconnected with any interest or advantage to be derived from the knowledge acquired. Every one is amused with reading a story: a romance may please some, and a fairy tale may entertain others; but no benefit beyond the amusement is derived from this source: the imagination is gratified; and we willingly spend a good deal of time and a little money in this gratification, rather than in rest after fatigue, or in any other bodily indulgence. So we read a newspaper, without any view to the advantage we are to gain from learning the news, but because it interests and amuses us to know what is passing. One object, no doubt, is to become acquainted with matters relating to the welfare of the country; but we read the occurrences which do little or not at all regard the public interests, and we take a pleasure in reading them. Accidents, adventures, anecdotes, crimes, and a variety of other things amuse us, independent of the information respecting public affairs, in which we feel interested as citizens of the state, or as members of a particular body. It is of little importance to inquire how and why these things excite our attention, and wherefore the reading about them is a pleasure: the fact is certain; and it proves clearly that there is a positive enjoyment in knowing what we did not know before; and this pleasure is greatly increased when the information is such as excites our surprise, wonder or admiration. Most persons who take delight in reading tales of ghosts, which they know to be false, and feel all the while to be silly in the extreme, are merely gratified, or rather occupied, with the strong emotions of horror excited by the momentary belief, for it can only last an instant. Such reading is a degrading waste of precious time, and has even a bad effect upon the feelings and the judgment.—But true stories of horrid crimes, as murders and pitiable misfortunes, as shipwrecks, are not much more instructive. It may be better to read these than to sit yawning and idle—much better than to sit drinking or gaming, which, when carried to the least excess, are crimes in themselves, and the fruitful parents of many more. But this is nearly as much as can be said for such vain and unprofitable reading. If it be a pleasure to gratify curiosity, to know what we were ignorant of, to have our feelings of wonder called forth, how pure a delight of this very kind does Natural Science hold out to its students? Recollect some of the extraordinary discoveries of Mechanical Philosophy. How wonderful are the laws that regulate the motions of fluids! Is there any thing in all the idle books of tales and horrors more truly astonishing than the fact, that a few pounds of water may, by mere pressure, without any machinery, by merely being placed in a particular way, produce an irresistible force? What can be more strange, than that an ounce weight should balance hundreds of pounds, by the intervention of a few bars of thin iron? Observe the extraordinary truths which Optical Science discloses.—Can any thing surprise us more, than to find that the colour of white is a mixture of all others—that red, and blue, and green, and all the rest, merely by being blended in certain proportions, form what we had fancied rather to be no colour at all, than all colours together? Chemistry is not behind in its wonders. That the diamond should be made of the same material with coal, that water should be chiefly composed of an inflammable substance; that acids should be almost all formed of different kinds of air, and one of those acids, whose strength can dissolve almost any of the metals, should be made of the self-same ingredients with the common air we breathe; that salts should be of a metallic nature, and composed, in great part, of metals, fluid like quicksilver, but lighter than water, and which, without any heating, take fire upon being exposed to the air, and, by burning, form the substance so abounding in salt-petre and in the ashes of burnt wood: these, surely, are things to excite the wonder of any reflecting mind—nay, of any one but little accustomed to reflect. And yet these are trifling when compared to the prodigies which Astronomy opens to our view: the enormous masses of the heavenly bodies; their immense distances; their countless numbers and their motions, whose swiftness mocks the uttermost efforts of the imagination.

* * * It is surely a satisfaction, for instance to know that the same thing, or motion, or whatever it is, which causes the sensation of heat, causes also fluidity, and expands bodies in all directions; that electricity, the light which is seen on the back of a cat when slightly rubbed on a frosty evening, is the very same matter with the lightning of the clouds;—that plants breathe like ourselves, but differently by day and by night;—that the air which burns in our lamps enables a balloon to mount, and causes the globules of the dust of plants to rise, float through the air, and continue their race;—in a word, is the immediate cause of vegetation. Nothing can at first view appear less like, or less likely to be caused by the same thing, than the processes of burning and of breathing—the rust of metals and burning—an acid and rust—the influence of a plant on the air it grows in by night, and of an animal on the same air at any time, nay,

and of a body burning in that air; and yet all these are the same operation. It is an undeniable fact, that the very same thing which makes the fire burn, makes metals rust, forms acids, and causes plants and animals to breathe; that these operations, so unlike to common eyes, when examined by the light of science, are the same —the rusting of metals—the formation of acids—the burning of inflammable bodies—the breathing of animals—and the growth of plants by night. To know this is a positive gratification. Is it not pleasing to find the same substance in various situations extremely unlike each other;—to meet with fixed air as the produce of burning—of breathing—and of vegetation;—to find that it is the choak-damp of mines—the bad air in the grotto at Naples—the cause of death in neglected brewers' vats —and of the brisk and acid flavor of Seltzer and other mineral springs? Nothing can be less like than the working of a vast steam engine, and the crawling of a fly upon the window. We find that these two operations are performed by the same means, the weight of the atmosphere, and that a sea-horse climbs the ice-hills by no other power. Can any thing be more strange to contemplate? Is there in all the fairy tales that ever were fancied, any thing more calculated to arrest the attention and to occupy and to gratify the mind, than this most unexpected resemblance between things so unlike to the eyes of ordinary beholders? What more pleasing occupation than to see uncovered and bared before our eyes the very instrument and the process by which nature works? Then we raise our views to the structure of the heavens; and are again gratified with tracing accurate but most unexpected resemblances Is it not in the highest degree interesting to find, that the power which keeps this earth in its shape and in its path, wheeling round the sun, extends over all the other worlds that compose the universe, and gives to each its proper place and motion? that this same power keeps the moon in her path round our earth, and our earth in its path round the sun, and each planet in its path? that the same power causes the tides upon our earth, and the peculiar form of the earth itself; and that, after all, it is the same power which makes a stone fall to the ground? To learn these things, and to reflect upon them, fills the mind, and produces certain as well as pure gratification.

---

* Tartar is procured from vessels in which wine has been kept. The tartaric acid appears to be a necessary substance in all wine; for it seems from some late experiments that *must* will not ferment if all the tartaric acid be taken from it.

All the vegetable acids seem to be formed from the same radicals, viz: carbon and hydrogen, and perhaps in some there is also nitrogen: the different proportions of these, as well as of the oxygen, constitute the whole varieties.

† Within these few years an important use has been made of this acid in medicine. It is said that the largest dose of opium may be checked in its narcotic effects, if a proper quantity of citric acid be taken with it; and that with this adjunct it induces cheerfulness instead of stupefaction, succeeded by gentle and refreshing sleep. Dr. Willich's *Lecture on Diet and Regimen*, page 339.

‡ The malic acid is found not only in apples, but in strawberries and other summer fruits.

§ The acids are such powerful agents in a variety of chemical changes which take place in nature and in the arts, that it is of the utmost importance to acquire a knowledge of the modes in which they operate. Let it be recollected, then, that there are two ways in which the acids produce changes in the substances with which they are brought into contact. In some cases they effect a union with these substances, and become a part of the new compound, without having themselves undergone any decomposition. In others they become partially decomposed, by affording a part of their oxygen to the bodies on which they operate. The formation of saltpetre or nitre by the addition of nitric acid to potash is an instance of the first of these cases, and the action of the same acid on iron will exemplify the latter.

* Sulphuric acid, in a diluted state, is used by the tanner in the operation called scouring; also by the dyer, in a concentrated state, for dissolving indigo. It is likewise employed by hatters. Silk-dyers use it for whitening silks, and for giving them a beautiful lustre. The chemist employs it in the preparation of nitrous and muriatic acid, and as an agent in a variety of processes and decompositions. An account of a great variety of other purposes to which sulphuric acid is applied in the arts may be seen in my *Chemical Essays*, vol. ii. page 468.

Nitric acid is used by dyers to make their solutions of tin. Silver-refiners employ it in the operation of *parting*. It is also used by gilders, brass-founders, calico-printers, colour-makers, &c.

Muriatic acid is employed in dying, calico-printing, and colour-making. The oxymuriatic acid, in bleaching, and sometimes in medicine.

† The acetic, oxalic, tartaric, citric, gallic, and prussic acids are all of them employed in the different manufactures of the country.

‡ The acetic, the tartaric, and the citric acids are used for culinary purposes. According to some experiments of Dr. Macbride, it appears that all the mineral acids in a diluted state might be employed with great advantage in preserving meat.

§ Parliament voted a reward of £5000 to Dr. Carmichael Smyth, for his discovery, that nitrous acid, applied in a state of vapour, effectually destroys contagion, especially typhus, jail, yellow, and such like fevers. See Dr. Smyth, on *The Effect of Nitrous Vapour*, 8vo. 1799.

‖ Limestone, chalk, and marble, are composed of about 44 parts carbonic acid, and 56 parts lime.

¶ Gypsum is composed of 41½ parts of lime, and 58½ of dry sulphuric acid.

** Dr. Thomson analyzed a specimen of fluor spar from Northumberland, and found it to consist of lime 67.34, and fluoric acid 32.66.

†† Common salt, when in a state of purity, is composed of 53½ parts soda and 46½ of dry muriatic acid; but the salt of commerce is always impure.

‡‡ If the pupil be directed to pour a little diluted sulphuric acid upon some pieces of marble, the carbonic acid will be disengaged, and become evident to the senses. In like manner, he may disengage the fluoric acid from the fluor spar, the muriatic acid from rock-salt, and other acids from those minerals in which they are found native. A few experiments of this kind will serve to show him how abundantly the mineral acids occur in nature.

§§ Celestine, which occurs in such large quantities in the neighborhood of Bristol, is composed of about 57 per cent. of strontites, and 43 per cent. of sulphuric acid.

‖‖ Ponderous spar, which is found plentifully in Staffordshire, Derbyshire, &c. and there called *cawk*, is a compound of 67 per cent. of barytes, and 33 of sulphuric acid. The granular kind consists of 90 per cent. of sulphate of barytes and 10 of silica.

¶¶ The *cryolite*, which is a very rare mineral, found only in a dreary and remote region of West Greenland, is, according to Vauquelin, composed of 21 per cent. of alumina, 32 of soda, and 47 of fluoric acid.

* * * Let any man pass an evening in listless idleness, or even in reading some silly tale, and compare the state of his mind when he goes to sleep or gets up next morning, with its state some other day, when he has passed a few hours in going through the proofs, by facts and reasoning, of some of the great doctrines in Natural Science, learning truths wholly new to him, and satisfying himself by careful examination of the grounds on which known truths rest, so as to be not only acquainted with the doctrines themselves, but able to show why he believes them, and to prove before others that they are true—he will find as great a difference as can exist in the same being; the difference between looking back upon time unprofitably wasted, and time spent in self-improvement: he will feel himself in the one case listless and dissatisfied, in the other comfortable and happy; in the one case, if he do not appear to himself humbled, at least he will not have earned any claim to his own respect; in the other case, he will enjoy a proud consciousness of having, by his own exertion, become a wiser and therefore a more exalted creature.—*Lord Brougham.*

VALUABLE PROPERTY at Saratoga Springs, for sale.—The following highly desirable pieces of property, with the improvements thereon, are offered for sale, comprising about 550 acres of land, viz:

The premises known as the MANSION HOUSE, situated about one mile east of the village. The building is a large commodious edifice, recently fitted up and furnished for a genteel boarding establishment, having a front of sixty feet, with double piazza and colonnade. Connected with the main building is a wing, making together a depth of about ninety feet. There are thirty lodging rooms, some of which are spacious, two parlors, &c. a dining hall, capable of accommodating 100 guests. Attached to the premises are a large barn, carriage-house, stables, wood and ice-house, &c. &c. large garden, with fruit trees and shrubbery. There will be sold with the above, from 75 to 100 acres of land, as may be desired, including the celebrated TEN MINERAL SPRINGS, only a few rods distant. The superior quality of these waters is too well known to require a particular description here. The Washington fountain is not inferior in its medicinal properties to any in the county of Saratoga, having been much resorted to, and is daily gaining in public estimation. Immediately contiguous to these springs, there are fifteen acres of table land, which from its high situation, commanding an extensive range of fine mountain scenery, presents very eligible sites for the erection of gentlemen's summer residences, or for a public institution.

Also, for sale, the handsome neat cottage adjoining the Mansion House, with stable, shed, store-house, &c. and from 20 to 75 acres of land.

Also, the valuable farm known as the Gibbs' Lot, on which is a comfortable and convenient farm-house, large barn, &c. embracing from 100 to 150 acres of land. It is well watered, and in every respect, a very desirable farm.

The residue of the land, situated in the vicinity of the above, will be divided in such a manner as to suit applicants.

Also, in the town of Northumberland, 80 acres of land, near Gansevoortsville.

Also, a good building lot in the village of Washington, or Watervliet.

On a part of the foregoing described property, (less than a mile from the village of Saratoga Springs,) is a very valuable water power, which could command a large amount of business, if suitable mills were erected. The line of the Whitehall rail-road, (which has been commenced,) is laid through the premises for more than a mile, and passes within a convenient distance from the Mansion House, and from the facilities it will afford, when completed, it is believed will greatly enhance the value of the property.

For terms and further particulars, apply to W. L. F. WARREN, Esq. Saratoga Springs, or H. H. & R. LAWRENCE, No. 10 Cedar-street, New-York.

FOR SALE—The short horn Durham Bull, SUPERIOR. He was calved in August, 1831. Superior was got by Frederick,* dam, Yellow Rose, by Young Denton; grand dam, Arabell, (imported) North Star; great grand dam, Aurora, (imported) Comet; great, great grand dam, Aurora, (imported) Henry; great, great, great grand dam, Aurora, (imported) Danby.

Price $250, apply to C. N. Bement, Esq., or to
WILLIAM A. S. NORTH,
Mont Marie, Duanesburgh, N. Y., where the Bull and his stock may be seen.

* Frederick was got by Wye Comet.

PAPER HANGINGS.—The subscribers offer to country merchants, a large assortment of paper, both French and American, on as good terms, and at as low prices as can be had in New-York or elsewhere. On the opening of navigation, they will receive upwards of seventy cases of French paper, of their own importation, including Borders, Fire Board Prints, &c. Dealers are invited to call and examine, at 419 South-Market-street, Albany. LEMUEL STEELE & SON.

FRESH GARDEN SEEDS.—The subscriber is now ready to receive orders in his line to any extent, having just received (in addition to a large stock of seeds of American growth of the present season) by various arrivals, a large assortment of English seeds, among which are early York, Battersea and drumhead cabbage; Windsor beans; the finest early and late peas; radish seed, sorts; true French sugar beet, (this from France;) genuine English mangel wurtzel; white mustard seed for medicinal purposes, very clean; rape seed; canary seed; lucerne; white Dutch clover; orchard grass, &c.

Those who may wish to favor the subscriber with their commands, may depend on the genuine quality of every article, as none other are retained—nor are old seeds kept on hand to be mixed with new, but are thrown away as soon as the new comes in, an adherence to which rule has made the seed trade, commenced by my father twenty-five years since, with a half pound of cabbage seed and a few ounces of other varieties, (in all $15) grow to its present standing, which it is no boast to state, is one of the best establishments in this country, and exceeded by but few in Europe.

It will always be the aim of the subscriber to merit a continuance of public patronage, bestowing as much pains on an order for $1 as for $100, to both which he he gives his personal attention. The prices, both wholesale and retail, are as low as any in America. Catalogues for private, and price currents for trade customers, can be had on application.

☞ Orders will be punctually attended to, and carefully packed and forwarded as directed, but as the collection of distant debts are often troublesome and sometimes impracticable, it is desired that all orders be accompanied with the money. W. THORBURN,
Market-street, corner of Maiden lane.

SEEDS AND TOOLS, wholesale and retail, for sale at the seed store of Ellis and Bosson, No. 34 North-Market-street, Boston, Mass. For sale a full assortment of seeds of all kinds. Tools and implements of the most approved patterns. A list of the whole, with directions for the culture of important varieties of seeds, and a description of the implements named, is given in a book catalogue of 80 pages, which will be furnished to applicants gratis.

Orders by mail will receive prompt attention. Address ELLIS & BOSSON, Boston, Mass.

RUGGLES, NOURSE & MASON, Worcester, Mass. manufacture extensively, seven sizes of their celebrated Long Worked Cast-Iron Ploughs, for which the American Institute, at their late annual fair, in the city of New-York, awarded the prize medal for the best and most perfect specimens of ploughs.

They also manufacture four sizes of their improved Side-hill or Swivel Plough. Paring Ploughs, used in reclining meadows or swamps; improved expanding Cultivator or Horse Hoes; three kinds of Seed Sowers; Hay and Straw Cutters; Cast-steel Garden Trowels; Garden Hoes and Rakes, &c. &c.

MESSRS. C. & A. J. DOWNING, of Newburgh, N. Y., offer for sale genuine Brussa mulberry trees, raised by cuttings from the original trees brought from Brussa by Mr. Rhind. These trees are very hardy, and are therefore highly suitable for the northern and eastern states. Size from 1 to 4 feet, and price from 30 to 60 cents, according to size.

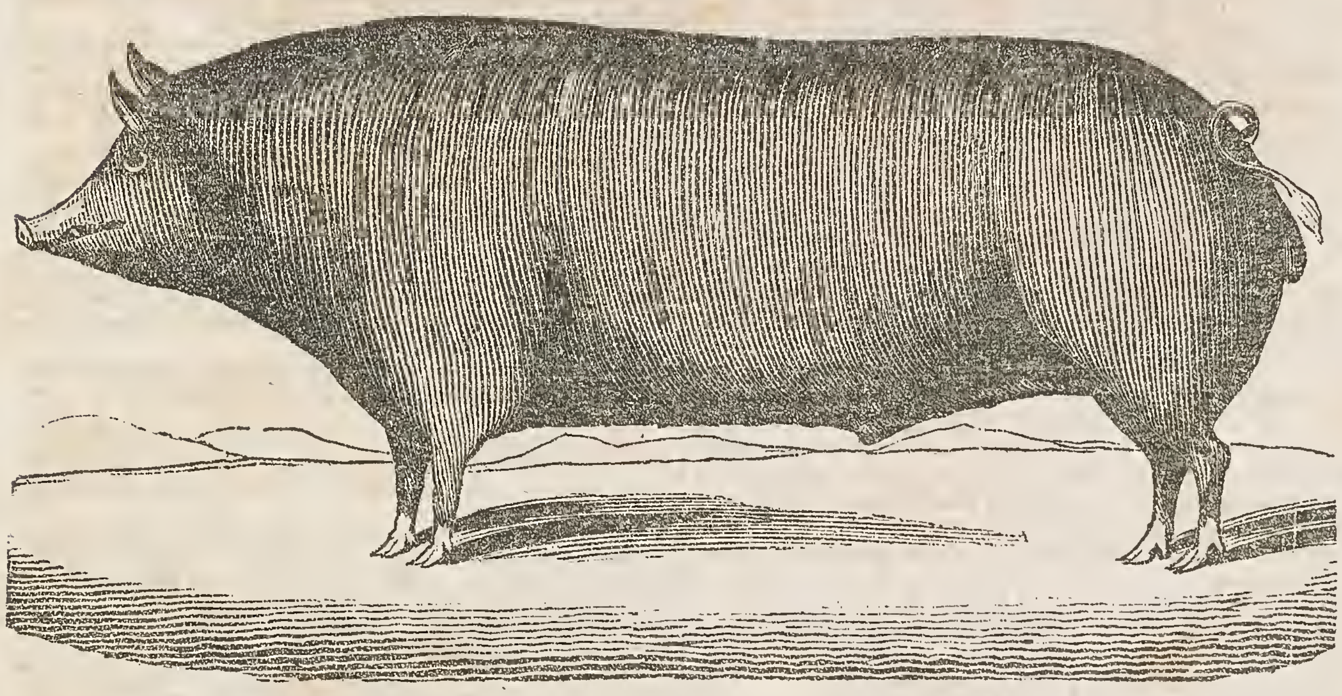
ROCHESTER SEED STORE, 1839.—REYNOLDS & BATEHAM, the proprietors of this well known establishment, respectfully announce that they have again on hand a fine assortment of English and American SEEDS, of the latest growth, including all the most valuable and newly introduced articles of garden and field culture—grain, grass, esculent vegetables, tree, shrub, herb and flower seeds. Also, a large collection of garden tools, agricultural and horticultural implements, books, &c. and a splendid collection of green house plants.

The liberal and constantly increasing patronage which this establishment has received during the past four years, is a gratifying evidence that its usefulness is in a measure appreciated by an intelligent community, and that the efforts of the proprietors to give satisfaction have not been unsuccessful. Great pains are taken to have all articles sold at this establishment of the very best quality, and the proprietors hope, by unremitted exertion, together with their experience in the business, and facilities for growing and importing supplies, to merit the fullest confidence of the community, without which they do not ask or expect a continuation of its liberal patronage. Merchants and others supplied with superior seeds, either by weight at wholesale, or neatly put up in small papers for retailing, at prices which will afford them a handsome profit. Small assortments will not be furnished on commission, but an agency is, or will be established in each of the principal villages in western New York, where a full assortment will be left for sale.

A catalogue of 42 pages may be had on application.
REYNOLDS & BATEHAM,
No. 3 & 5 Arcade Hall, Rochester, N. Y.

SHAKER SEEDS, for sale by WIGHT & GIBSON, Druggists, No. 44 Hanover-street, under the American House, Boston. All kinds of garden seeds cultivated by the United Society, at Harvard, Mass. and put up with directions for culture by Jonathan Chandler, trustee for said society. Persons purchasing to sell again, can have these seeds at the same price as sold them by the society at Harvard, or by their travelling agent.

BERKSHIRE PIGS! BERKSHIRE PIGS!!



BERKSHIRE PIGS.—Persons wishing to purchase genuine Berkshire pigs, are requested to call on the subscriber, No. 253 Washington-street, Albany, and examine mine. My stock are from the original importation made by Mr. Hawes; and I have three of genuine blood, two males and one female, selected by the same gentleman in England, and imported in November last, unrelated to the old stock. I went to the expense of importing them expressly for the purpose of improving those we had here. An opinion of the quality of these pigs may be formed from the fact notified to me by Wm. P. Curd, of Lexington, Ky. asking the pedigree of four, two of which I sold to Mr. Bryant of that state in 1836, for which he (Mr. Curd) paid Mr. Bryant $500—also of one that I sold James E. Letson, Esq. in 1837, and one that he bought of Mr. Hawes at the same time, for which two Mr. Curd paid Mr. Letson $300. Mr. Curd further writes, that he had sold eighty-five pair of pigs, from this stock, for $3400. Mr. Beach also writes me from Ohio, that the male and 20 pigs I sold him last spring, had established their reputation in that state as to size, the former having weighed at the fair last October, 550 pounds, and that he took the premium of a silver pitcher valued at 25 dollars.—He was about 17 months old at the time.

John Lossing.

BERKSHIRE PIGS.—ORIGINAL STOCK.—The subscriber has still in his possession, three of the original Berkshire hogs, imported in 1832. Also, several sows, descended from the above and the first imported boar, all of which are expected to litter in April next. Two of the above young sows have been crossed with a Berkshire boar, lately imported by Mr. John Lossing.

Gentlemen desirous of obtaining this valuable breed, in its purity, are requested to make early application. "First come, first served." ☞ Those making remittances in advance, will have the preference.

For a description of this very superior breed of hogs, I would beg leave to refer to the present and former volumes of the Cultivator.

Price—Pigs from 6 to 8 weeks old, $21 per pair, including a cage to send them in, delivered in Albany, after which they will be at the expense and risk of the purchaser.

DURHAM CATTLE.—A few head of the "improved short horned Durham cattle," consisting of cows, heifers and calves—one two year old bull and one bull calf, six months old—all thorough bred, and good pedigrees. Also, eight SOUTH DOWN BUCKS, bred from the stock imported by Mr. Hawes. For sale by

Caleb N. Bement, Three Hills Farm, Albany.

BERKSHIRE AND IMPROVED CHINA PIGS, for sale.—The subscriber keeps constantly on hand the above celebrated breeds of hogs. His stock is of perfect purity of blood, and as choice animals as can be found in the country, having been selected at great pains and without regard to price. He would especially commend his China boars to the attention of breeders, as they are so broad and deep in the carcass, so fine in all their points and so easily kept, that crossed with the most ungainly animals of the country, their stock is more rapidly improved than it could possibly be from any other breed whatever. The improved Chinas are celebrated for the delicacy and sweetness of their meat, and will return more pork for the same amount of food than any other race of hogs known; a matter of no trifling importance to the breeder. The Berkshires are too well known to need description.

Residing, as the subscriber does, at the great shipping port of the lakes, western gentlemen in addressing their orders to him, will make a considerable saving in in the item of transportation.

A. B. Allen, Buffalo.

BERKSHIRE PIGS.—A. & G. Brintnell, of Canterbury, Orange county, New York, keep pure bred Berkshire pigs for sale, at the following prices, viz: last fall pigs on the opening of navigation, $30 per pair; spring pigs ready for delivery in May next, at $10 per pair; with $1 extra for the box when delivered on board one of the North River Boats, at Newburgh.

Also, for sale a superior improved Durham short horned bull calf, one year old in May next, a beautiful roan colour, and having a cross in him of five pure bred imported bulls, viz: Admiral, Denton, Wye Comet, Dishley and Durham. Price $150.

BERKSHIRE PIGS.—The subscribers having increased their number of breeding hogs, will continue to receive orders for pure blood Berkshire pigs, to be filled during the spring, summer and fall of the present year. Orders for the south can be forwarded to N. York, by sloops or steam-boats every day in the week, (Sundays excepted,) during the season of navigation. Letters of inquiry must be post paid to insure attention. We have now on hand and for sale, a boar of the above breed, nearly two years old.

H. & J. Carpenter, Norwich, Conn.

FOR SALE.—A few pair of full blood Berkshire Pigs, from the stock of C. N. Bement, and from newly imported stock. A few pair of the full blood grass breed pigs are expected this summer. Also, this spring, pigs of the Berkshire breed, crossed with the China, grass, and Byefield breeds. One pure blooded Paular Merino buck. One pure blooded Bakewell buck.

Letters and orders, post paid, directed to S. M. Mitchell, Norwich, Conn. will meet with prompt attention.

CONGRESS HALL, Park-Place, corner of Washington-street, in the immediate vicinity of the Capitol, state offices and rail-road. W. Landon.

FRANKLIN HOUSE, opposite the rail-road office, in the immediate vicinity of the Capitol and state offices. Lately thoroughly repaired and improved; 136 State-street. A. Freeman.

CITY HOTEL, Albany, N. Y.—This extensive establishment has been recently enlarged; is situated in the most populous and pleasant part of the city, near to the post-office, banks, baths, rail-road and steam-boat landings. No charge for carrying baggage.

Chapin & Foster.

AZOR TABER and AMOS DEAN, Attorneys and Counsellors at Law, under the firm name of A. Dean, Commercial Buildings, S. Market-street, Albany.

ROBERT J. HILTON, Judge of Albany Co. Courts, Counsellor at Law, and ex-officio a Supreme Court Commissioner, office State-street, Albany, will promptly attend to all kinds of professional and official business that may be entrusted to his care.

WM. & A. GOULD & Co. Law Booksellers, No. 104 State-st. Albany, and Gould, Banks & Co. Law Booksellers, New-York, have constantly on hand, at both of their stores, a very general assortment of law books, law blanks and stationery articles, which they will afford as low as any other dealers.

THEOLOGICAL and Sabbath School Book Store.—Erastus H. Pease, Bookseller and Stationer, No. 82 State-street, Albany. English and American theological works, comprising a large and choice collection—the publications of all the Sabbath school societies—of the American, the Presbyterian and London tract societies—all new valuable works, and a general assortment of stationery, blank books, &c. ☞ Ledgers, journals, day books, letter books, registers, cash books, invoice books, bill books, receipt books, &c. Merchants, forwarding houses and public offices supplied with books and stationery of the best quality, on liberal terms.

JAMES HENRY, Bookseller, Stationer and Blank Book manufacturer, No. 71 State-st. Albany, keeps constantly on hand, day books, journals, ledgers, cash books, invoice books, registers, letter books, and a general assortment of half bound books of all sizes.

FRESH GARDEN AND FIELD SEEDS FOR 1839. We are now receiving and have for sale at our Seed Store and Agricultural Warehouse, No. 7 Merchants' Row, (3 doors from State-street) our supply of new seeds for the present year, comprising one of the largest and most extensive assortments, and including all the newest and best varieties of Corn, Potatoes, Wheat, &c. Having been for upwards of ten years engaged in the business of raising seeds, we can with confidence recommend our stock to be pure and of the best quality, having been raised by us, or by experienced growers expressly for us.

The following comprise some of the numerous varieties for sale:

100	bushels	best early peas,
100	"	large dwarf marrowfat do.
50	"	dwarf blue imperial do.
50	"	other fine varieties do.
100	"	of the best sorts of garden beans, dwarf and pole,
1000	pounds	long blood beet,
300	"	early turnip rooted do.
500	"	mangold wurtzel and sugar beet,
300	"	long orange carrot,
100	"	large Altringham do.
300	"	large Dutch parsnip,
500	"	ruta baga,
500	"	English turnip; 200 do. other varieties,
200	"	large red onion,
100	"	yellow do.; 50 do. pure white do.
200	"	early cabbage seed, of different sorts,
200	"	large drumhead and Savoy cabbage, (of American growth,)
500	"	long prickley cucumber,
500	"	early varieties do.
150	"	lettuce, the best sorts,
200	"	early squash, different sorts,
200	"	winter and Canada crookneck squash
100	"	autumnal marrow do.
300	"	short top radish,
200	"	long salmon, and other varieties do.
100	"	tomato,
25	"	squash pepper, (thick skin,)
100	"	different sorts melons,
500	bushels	Dutton corn; 200 do. Parker do.
100	"	ears sweet corn,
500	ears	Chinese do. (new.)

Also, celery, cauliflower, cress, brocoli, egg plants, okra, endive, leek, parsley, spinach, sweet marjoram, summer savory, thyme, salsify, sage, &c.

Herds Grass, Red Top and Clover Seed, at wholesale and retail.—Lucerne, orchard grass, rye grass, millet, spring and winter wheat, rye, oats, barley, buckwheat, seed corn, Rohan and other sorts of potatoes, &c. &c.

Among the varieties of corn, the "Parker" sustains a high character, and is remarkable for the length of the ear, the size of the kernel, and its great product. The Chinese, or tree corn, a new variety, has also been highly recommended for its earliness and great yield.—The Dutton is already well known. And the Rohan potato is one of the most remarkable products ever introduced.

Boxes of Garden Vegetable Seeds put up for dealers, containing a complete assortment, in papers, ready for retailing, with printed labels and directions, for cultivation, furnished either on commission or otherwise, on as good terms as at any other establishment.

Also, seeds for the West Indies or western islands, put up in boxes, with the names in English, French and Spanish.

Flower Seeds.—Upwards of 100,000 packages of annual, biennial, and perennial flower seeds are annually put up and ready for sale. Among them are all the new and choice varieties. The beauty of our double German Asters, Rocket Larkspurs, Zinnias, and similar showy flowers, are too well known to need any description here.

Assortments of 20 varieties, each one labelled with directions for planting, are neatly put up in boxes and sold at one dollar per box.

Splendid Double Dahlias.—200 varieties of this most beautiful flower (of which a separate catalogue is issued every spring) comprising all the newest and most splendid varieties to be procured in England. Dry roots supplied at the lowest prices.

Greenhouse Plants, always ready for sale from our garden, including a large collection of the finest Camellias, Ericas, Roses, Geraniums, Verbenas, &c. to be found. Plants suitably packed so as to be transported to any part of the country.

Bulbous Roots of all descriptions. Hyacinths, Tulips, Pœonies, Gladiolus, Amaryllis, &c. &c.

Rhubarb and Asparagus Roots, Strawberry plants by the dozen or thousand; also, Gooseberry, Raspberry, and Currant bushes of the most select kinds we have growing, and can supply in any quantity.

Fruit and Ornamental Trees furnished from the best nurseries in the vicinity of Boston, at one day's notice, at catalogue prices.

Morus Multicaulus Trees and cuttings, for sale by the hundred or thousand.

Garden Implements and Books on Gardening and Agriculture, constantly for sale.

Catalogues furnished gratis.

☞ Orders sent by mail or otherwise, with a remittance or reference will receive prompt attention and despatch, and be faithfully executed.

Hovey & Co.,
Seed Store and Agricultural Warehouse, No. 7, Merchants' Row, Boston.

NEW-ENGLAND AGRICULTURAL WAREHOUSE, Seed Store, and Office of the New-England Farmer, No. 51 and 52 North Market-street, Boston. JOSEPH BRECK & Co., the proprietors of this establishment would inform their friends and the public, that they keep constantly on hand and for sale, the greatest variety of Agricultural Implements, Grass Seeds, Garden and Flower Seeds, Bulbous Roots, Double Dahlias, &c. &c. to be found in the country;—among which are the following

Agricultural Implements.

C. Howard's Cast Iron Ploughs, Tices' do., Side Hill do., Double Mould Board do., Wrought Iron and Wooden Ploughs, Scott Keith, and other Plough Castings, Willis's improved Cultivator, Green's Patent Straw Cutter, Willis's do., Common hand do., Manure and Hay Forks, Scythes of all kinds, Patent and other Snaiths, Hall's and other Hay Rakes, Grindstones on Rollers, Corn Shellers, Grain Cradles, Chains of all kinds, Willis's improved Seed Sower, Gault's Patent Churns, Self Operating Cheese Press, Horse Power and Threshing Machine, Davis's Road Scrapers, Hale's Rotary Pump, Lead Pipe, Force Pumps, Copper do., Iron do., Underhill's Cast Steel Axe, Bark Mills, Corn and Cobb Mills, Harris's Paint do., Winnowing do., Grater Cider do., Cast Iron Cider Screws, Yokes of all kinds, with a great variety of Agricultural and Horticultural tools, too numerous to mention.

Field Seeds.

Northern Clover, Southern do., White Honeysuckle Clover, Lucerne, Herds grass, or Timothy, Red Top Southern Seed, do. Northern do., Fowl Meadow, Orchard Grass, Ruta Baga, Mangel Wurtzel, Sugar Beet, &c., Winter and Summer Wheat, do. do. Rye, Barley, Oats, English, Corn of various sorts, Millet, Hemp, Flax Seed, Potatoes.

Garden Seeds,

Of every desirable variety will be furnished wholesale and retail; by the pound, box, or package.

Seeds in Boxes,

For retailing, done up in the neatest manner in packages, with the name and directions printed on each parcel. Retailers supplied on the most favorable terms, with boxes from $1 to $100.

For the Flower Garden,

We have a very extensive collection of choice Flower Seeds, embracing all the Annuals, Biennials, and Perennials worthy of cultivation. Packages of twenty fine sorts for one dollar.

Dutch Bulbous Roots.

We import of these annually from Holland, a splendid collection, consisting of double and single Hyacinths, double and single Tulips, Crown Imperials, Narcissus, Iris, Crocus Gladiolus, Amaryllis, Ixias, &c. &c.

Double Dahlia Roots.

Of this beautiful and popular flower, we have more than two hundred fine varieties, embracing all that were shown at the exhibition of the Massachusetts Horticultural Society. Roots can be furnished from the first of October to the first of July, safely packed in moss, and sent to any part of the country.

Fruit and ornamental Trees and Shrubs furnished to order at Nursery prices.

Large plants of the Morus Multicaulis, and cuttings of the same, can be furnished by the hundred or thousand at moderate prices.

We would call the attention of the public to the New-England Farmer; one of the oldest and best agricultural newspapers in the country, containing a great amount of interesting and useful matter for the practical farmer and gardener. It is issued at our office weekly, on Wednesdays, at the moderate price of $2.50 per year in advance, or $3 at the close of the year.

We also publish the Horticultural Register, and Gardener's Magazine, issued monthly, at $2 per annum in advance, or $2.50 at the expiration of six months.—This work is devoted principally to the cultivation of Fruits, Vegetables and Flowers. New Subscribers can be supplied with the back volumes at $2.50 per vol. bound.

Among our agricultural Books we keep for sale, The Complete Farmer; Kenrick's Orchardist; American Gardener; Bridgman's Gardener's Assistant; Moubray on Poultry; Silk Grower's Guide; Cobb's Silk Manual; Loudon's Works, together with a great variety of useful and interesting works in this line.

We hope by unremitted attention, to sustain the credit of this establishment, and realize the anticipations of our predecessors, Newell, Russell & Barrett, in making it one of the most complete depositories for every thing in the Agricultural and Horticultural line in the country. JOSEPH BRECK & Co.

CHINESE AND BRUSSA MULBERRY SEED.—The subscribers have just received a small invoice of the above seeds, which they offer for sale wholesale and retail. RUSHTON & ASPINWALL,
86 William-street, and 110 Broadway, and 10 Astor House, New-York.

ISAAC BROWN, Wholesale and Retail Dealer in Stoves, Corn Shellers, Ploughs and Plough Castings, bar, sheet, hoop, band, nail and horse shoe iron, cast, English, German and American steel, cutlery and heavy goods, at the sign of the Plane, No. 128 State-street, opposite the English church, Albany.

THE VARIETY STORE, 392 South-Market-street. The subscriber has and intends constantly to have in his store, a general assortment of Fancy Goods, Baskets, Toys, Domestic Articles, &c. at wholesale and retail.

STEPHEN VAN SCHAACK.

WILSON'S Improved Patent People's Cooking and Parlor Stoves. The subscriber is now manufacturing, at his warehouse, all the varieties of the above named stoves, some of which have stood the test of years. The People's Cooking Stove possesses advantages which renders it superior to any thing of the kind ever before in use. The plan of operating with it is entirely new; the entire heat is thrown first under the four boilers, and then returning by means of an extra return flue, passes entirely around the oven without being divided, which makes it the best baking and boiling stove now in use. The oven is very large, capable of baking six loaves at a time if required. This stove has taken for three successive years, the highest prize at the American Institute Fair. The following certificate and names are presented to the public, as references; many more might be obtained, but these are deemed sufficient.

CERTIFICATE.

Mr. James Wilson—Sir—You wish my opinion of your new cooking stove, termed "the People's Stove;" my family are much pleased with it, and say, of the great number which they have had in use, yours is decidedly the best, not only on account of convenience, the perfect manner in which the cooking is performed, but also on account of the economy of fuel which it effects. Yours respectfully, J. BUEL.

Charles E. Dudley, Wm. McHarg, Wm. Mitchell, Chauncey Humphrey, Jesse Buel, Jr.	*Albany.*	Daniel Van Antwerp, John Van Antwerp, Thomas Calanan, James Tefft, J. W. Whitbeck,	*Coeymans.*
David Huxley, James Bailey, Gilbert Wemple, B. Clapper,	*Bethlehem.*	J. Callanan, M. Whitbeck, A. Wood, J. O. La Grange,	*New-Scotland.*
Isaac S. Wilbur, *Clifton Park.*		John Sands, *Cow-Neck, L. I.*	
		J. R. Coles, *Glen-Cove, L. I.*	
John C. Traver, *Nassau.*		Capt. J. Holmes, *Mystic, Ct.*	
T. F. Carman, *Oyster-Bay, L. I.*		Capt. G. Moore, *Lyme, Ct.*	
		Geo. Reed, *Deep River, Ct.*	

Our assortment consists of all the varieties of stoves now in use, both for coal and wood; among which are the Union and Three Boiler Guard Plate cooking stoves; (improvements have been made in these stoves which renders them superior to any of the kind in market;) six and nine plate stoves, open and plain tops; Franklins, Pyramid stoves of a great variety of patterns, suitable for churches, halls, parlors, counting houses, &c.; a variety of small coal burners. Grecian parlor grates, a new and most beautiful article. American, English and Russia sheet iron dripping pans, stove pipe, &c. all of which will be sold to dealers and others on as reasonable terms as any house in the city.

E. L. WATSON, No. 15 Greene-st. Albany.

AGRICULTURAL IMPLEMENTS

AGRICULTURAL REPOSITORY, corner of Maiden-lane and North Market-street, (three doors north of the post-office,) Albany.

The proprietor will be induced to extend it in all its various branches, for the accommodation of experimental and scientific farmers, by the introduction of new and useful implements of husbandry, and to furnish the practical farmer with the best tools for his business. An establishment of this kind not only serves the above purpose, but makes a depository for the inventive artizan to place his articles for exhibition and sale. Machinists and manufacturers will find it to their interest to place here articles for sale and inspection, as it will more readily bring them before the public.

The object of this establishment is to keep on hand for sale, all the useful and improved agricultural implements now in use, and the subscriber invites mechanics and others to place their implements here for sale. His accommodations will be ample and his charges moderate.

For sale, Green's Straw-Cutter, Adriance's Corn-Shellers, Scotch Ploughs, and Drill-Barrow, Bement's Expanding Cultivator and Turnip-Drill, Van Bergen's Cultivator, Wiley's and Conklin's Ploughs, Turnip-Hoes, Pudney's Revolving Horse-Rake, Potato-Hoes, Bement's Grain-Mill, Bushnell's Drill-Barrow, Slater's Corn-Sheller and Grinder, Merchant's Ruta Baga Drill, Garden tools &c. &c. &c.

W. THORBURN, Seedsman.

CHINESE TREE PROLIFIC CORN.—The subscriber has for sale at his store, No. 317 North Market-street, Albany, a supply of this new and excellent variety of corn, (some account of which, will be found in the November number, page 157, of the Cultivator,) price 25 cents per ear.—Also Rohan Potatoes, with a full supply of garden, field and flower seeds, growth 1838, also the Whitington, new white wheat. W. THORBURN.

WM. PRINCE & SON, will make sales of trees and cuttings of the genuine Chinese Morus multicaulis, Morus expansa, Alpine, Broussa, Canton and other varieties, deliverable to the purchasers, at such period in the spring as is convenient to them, and will enter into contracts accordingly. Prices and terms for the trees and cuttings will be forwarded, to all who may apply for them by mail, as well as prices of silk-worm eggs mulberry seeds, &c. The Multicaulis trees are remarkably vigorous, and as we first imported the genuine tree, purchasers are sure of obtaining the genuine kind. It is from this cause and from the great attention paid by them, that the trees they have sold have given universal satisfaction.

Flushing, near New-York, December 26th, 1838.

FARM FOR SALE.—The farm well known as the Bemus Heights farm, containing about 250 acres, about 40 acres of which are in wood, about 150 acres in meadow, and the balance tillable land. On the premises are a good dwelling-house, farm-house, barn-room about 300 feet in length, by 30 feet in width.

Any person disposed to purchase will please call and examine. E. DUNSCOMB, Bemus' Heights, Saratoga Co. N. Y.

ROHAN POTATOES.—This new and extraordinary variety of the potato, was introduced into this country from Switzerland two years ago.

The following are among the accounts which have been published respecting its wonderful qualities.

A writer in the Genesee Farmer says, one pound of seed planted in his garden, produced 136 lbs. 3 ozs; and 45 lbs. planted on 24 rods of ground, produced 58 bushels, being three times as many as the common kinds produced on the same space and quality of ground.

A gentleman from Connecticut, from 13 ozs. of seed produced 2½ bushels of potatoes, which weighed 144 pounds while other varieties, with similar soil and cultivation, did not produce more than half an ordinary crop, owing to the extreme dry weather. It is stated that some of these tubers sold for $1 each, at the New Haven Horticultural Fair.—Judge Buel (in the Cultivator) says we have cultivated them two seasons, and feel justified in recommending them as a valuable acquisition in our husbandry.

First—Because their quality for the table will justify it.—If not superior they are good. The flesh is yellow, solid, and of good flavor.

Secondly—Because they admit of a great economy in seed; two eyes sufficing (and many of the tubers have 30 to 40 eyes) to plant a hill, and three or four bushels to plant an acre of ground.

Thirdly—Because they require comparatively little labor in harvesting, a man being able to dig thrice as many of them in a day as of ordinary kinds. The tubers are very large, 110 of the largest of our crop completely filling a flour barrel. 27 bushels were dug in our presence in one hour, (the tops being pulled,) by one man at moderate labor.

Fourthly—Because they yield an abundant crop—from 85 rods of ground were gathered 175 bushels, while our common kind did not give us half a crop. One case has been stated to us, of a single potato producing a bushel, and another of its having produced a barrel at harvest.

☞ They are for sale at the Albany Seed Store, by

W. THORBURN.

A FARM FOR SALE, containing about 210 acres, situated a little more than half a mile west of the village of Pittsfield, Berkshire county, Mass. Said farm has been stocked with sheep for many years, but is well adapted for grain or grazing. It is well supplied with wood, timber, fruit, &c.

On the premises are a new and convenient brick-house, a farm-house, several barns, sheds for sheep, &c.

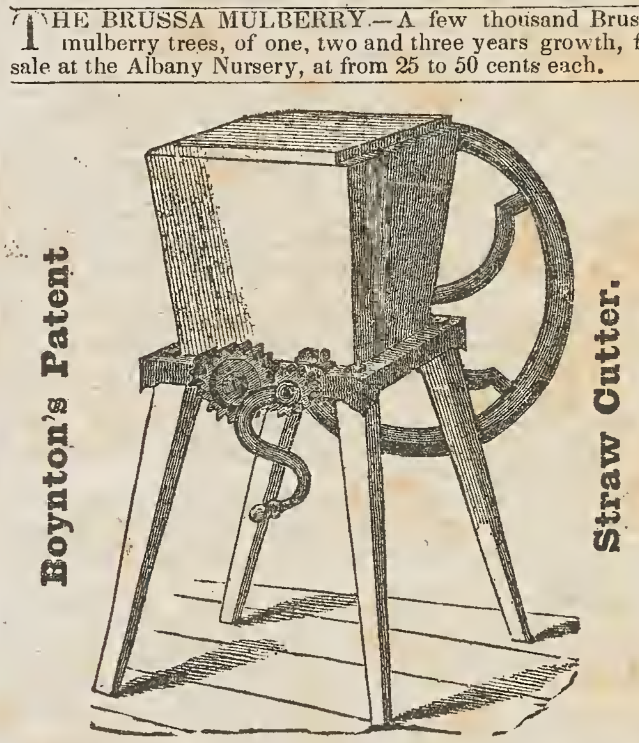
Also for sale, about half a mile north of said premises, a farm of 100 acres without buildings.

A very choice flock of Merino and Saxony Sheep, will be sold with the above farms if required.

Terms will be made easy. Apply to the subscriber on the premises. M. A. LEE.

ALBANY NURSERY.—The subscribers have for sale, as usual, a general assortment of Fruit and Ornamental Trees, Ornamental Shrubs, and Herbaceous and Green-House flowering Plants. Their stock of Pears and Plums is particularly good. A few hundred European mountain ash are offered low to the trade. J. BUEL & Co.

THE BRUSSA MULBERRY.—A few thousand Brussa mulberry trees, of one, two and three years growth, for sale at the Albany Nursery, at from 25 to 50 cents each.



BOYNTON'S PATENT STRAW-CUTTER.—This machine is designed for cutting straw, hay, cornstalks, &c. as food for cattle and horses, and may be useful for cutting many other articles. It may be driven with speed equal to two thousand turns a minute, making thirty-two thousand cuts, without doing the machine the least harm, while any other machine now in use for the same purpose, would be destroyed by running one hundred turns a minute.

The machine is constructed in a neat convenient and durable manner; is easily kept in order, and is adapted to either hand, horse, or water power; it is the only machine now in use that will run rail-road speed. Any person wishing to buy, may feel perfectly satisfied that no machine will ever supersede for utility and durability.

A machine may be seen at the Patent-Office, Washington city, Ellis & Bosson's agricultural warehouse 34 North Market-street, Boston, Baltimore, New-York city, Hartford, Ct. Hamilton Wool Co. Mill, Southbridge, Mass. and at the subscriber's factory in South Coventry.

Patent rights for counties, states, and territories for sale by the subscriber. JOHN BOYNTON, Patentee.

SMITH, STRONG & Co. (successors to R. Marvin & Co.) wholesale dealers in Foreign and Domestic Dry Goods, No. 421 and 423 S. Market-st. Albany.

EDWARD B. SLASON, Saddler, Harness and Trunk Maker, No. 90 State-street, Albany. Military work made to order. Horses measured and carefully fitted.

  Locust hedges—Peat earth—Hog-pen—Plans of houses—Planting trees—Shovel plough—Disease in calves—Grape culture—Tomatoes, 146
The farmer is neglected and forgotten, 102
— — should read and think, 105
The farrier, a valuable extract, 142
"The Memorial" noticed and recommended, 40
The mind and the Soil, 38
The season noticed, 67, 103
Tomatoes, instructions for preparation of, 134
— how to preserve for winter, 183
To our correspondents, 161
To our patrons, 65, 161, 177
Tow-path rail-way, utility of, suggested, 163
Transplanting roots, process of, 71
— trees, hints on, 85
Tropical Florida, 198
Turnips, culture of, 49
— injurious to horses—disputed, 44
— value of, 67
Useful mode of teaching, 33
Various matters considered, 133
Vegetable kingdom explained, 152
Vegetebles, artificial crossing of, 56
— crosses of, 119
Vegetation, phenomena of, considered, 158, 173
Water, novel plan of drawing, 181
Wealth, the result of industry and frugality, 143
We spread our nets too broad, 38
We thank our correspondents, 17
What is education? 39
Wheat, effects of steeping, 45
— product from one grain of, 148
— new white, remarks on, 106
— Santa-Fee, new variety, 25
— Whitington spring, noticed, 13
Whitewash, improved, recommended, 102
Whitmarsh's Silk Manual, 39
Wire ropes noticed, 53
Wool statistics of Vermont, 16
Women milking, 203
YOUNG MEN'S DEPARTMENT—*Hints to Young Farmers.*
  Despise not small things—time is capital, 64
  Self-culture, an address by Dr. Channing, 77, 96, 110
  Culture of the mind, 110
  Chemical Catechism—Salts, 126, 143
  — — Simple combustibles, 158, 175, 191, 206
  Year 1839, Close of, 206
Zinc roofs, objection against, 151

List of the Cuts.

No. 1. Smith's Subsoil Plough, 13
2. Tower's Cheese Press, 14
3. Drag or Harrow, 25
4. General Plan of a School House, 34
5. End view of Desks and Seats, 34
6. Plan of a Village School House, 34

TO THE FRIENDS OF EDUCATION.

Massachusetts School Library.

The peculiar merits of this Library, published by authority and under the sanction of the Mass. Board of Education, composed of many of the most distinguished literary men in our country, must, when known, be appreciated by every candid and intelligent mind. The publishers, in presenting it to the public and the friends of education, desire that it may be examined or compared with any other works published or republished, for the purpose of a school library, being confident that such an examination will result in convincing the trustees of the several school districts, and all impartially interested in securing books for the noble and important object of district libraries, of the great value and peculiar fitness of those composing this library.

It should be borne in mind that all these works are original, or prepared expressly for this library, at great expense, and with all possible care, by the most eminent authors of which our country boasts; nor is it unworthy of particular notice, that they are printed in large new type, on fine paper, and bound in a manner which has few examples for strength and excellence.

Among the distinguished individuals in this state, whose opinions are prized in reference to the merits of these volumes, may be mentioned His Excellency Wm. L. Marcy, Hon. John A. Dix, late Superintendent of Common Schools, Hon. Judge Buel, Hon. F. A. Talmadge, Hon. Gabriel Furman, Judge John B. Scott, Prof. B. F. Joslin, with the Superintendent of Common Schools of the state of Connecticut, and others. In addition to testimonials from such men, the North American Review, The Christian Examiner, The Monthly Miscellany, and other public journals, have been equally decided and commendatory in praise of this library. The American Institute has also awarded to this library its Medal.

Of the volumes already out of press, of the larger sizes, (and it should be observed that the publishers have not hurried their publication with the view to secure a market, but have carefully watched every progressive step to their completion, with the view only to secure the best books,) are, the Life of Columbus, with additions, illustrations, &c., 1 vol., by Washington Irving, Paley's Natural Theology, with Lord Brougham's and Sir Charles Bell's dissertations, with a life and portrait of the author, newly arranged and adapted by Prof. Bartlett, M. D; The sacred Philosophy of the Seasons, illustrating the wisdom of design in the natural world, in chapters for every day of the year, and describing and explaining all important and interesting facts and phenomena in Natural History and Science, with additions, &c., by F. W. P. Greenwood, 4 vols.; Lives of Eminent Men in American History, with illustrations, portraits, &c., 3 vols., by Prof. Jared Sparks; The Farmer's Companion, (an original work of great merit,) by Hon. Jesse Buel, 1 vol.; The useful Arts, by Prof. Bigelow, M. D., 2 vols.; The Pursuit of Knowledge, by the Rev. President Wayland, 2 vols.; A Familiar Treatise on the Constitution of the United States, by Hon. Judge Story, L. L. D. Several of the smaller series are also published and justly estimated.

Among the individuals already engaged as writers for one or both Series, may be mentioned—the Hon. Judge Story, Jared Sparks, Esq., Washington Irving, Esq., Rev. President Wayland, Professor Benjamin Silliman, Professor Denison Olmsted, Professor Alonzo Potter, Hon. Judge Buel, Dr. Jacob Bigelow, Dr. Robley Dunglison, Dr. Elisha Bartlett, Rev. Charles W. Upham, Rev. F. W. P. Greenwood, Rev. Royal Robbins, Rev. Warren Burton, Arthur J. Stansbury, Esq., E. C. Wines, Esq., Robert Rantoul, Jr., Esq., Professor Tucker, and Professor Elton.

Mrs. Sarah J. Hale, Mrs. E. F. Ellet, Mrs. Emma C. Embury, Mrs. A. H. Lincoln Phelps, Miss E. Robbins, Miss E. P. Peabody, Miss Mary E. Lee, Miss Caroline Sedgwick.

"The School Library" will embrace two series, of 50 volumes each, the one in 18mo. averaging from 250 to 280 pages per vol., at 40 cents, the other in 12mo. each containing from 350 to 400 pages, at 75 cents. The smaller, or juvenile series, is intended for youth of 10 or 12 years of age and under; the other, or larger series, for more advanced scholars, for adults or parents. It will include every department of literature and science, preference being given to works relating to and illustrating the history, the resources, and the institutions of our own country, and the manners, customs, and general character of our people. It being intended for the whole community, the Farmer, the Merchant, the Manufacturer, the Mechanic, the Housewife, and the Laborer, as well as the Professional man, will find instruction in their several employments. To accomplish objects so important, and with the view to render all more useful, respected, and happy, no pains or expense will be spared in the preparation of these works. The best talent in the country is secured, and the most liberal arrangements have been made to make the Library rich in History, Biography, Science, the Arts, Natural and Moral Philosophy, Natural History, Voyages, Travels, &c., with all the late and important discoveries and improvements, both at home and abroad, in Science, Agriculture, and in the useful, ornamental and domestic arts.

A Glossary, explanatory of foreign and scientific words, technical phrases, &c., will be attached to every volume requiring it: in addition to which, numerous and well executed cuts and engravings will illustrate the various subjects of the works, which may be made thereby more intelligible.

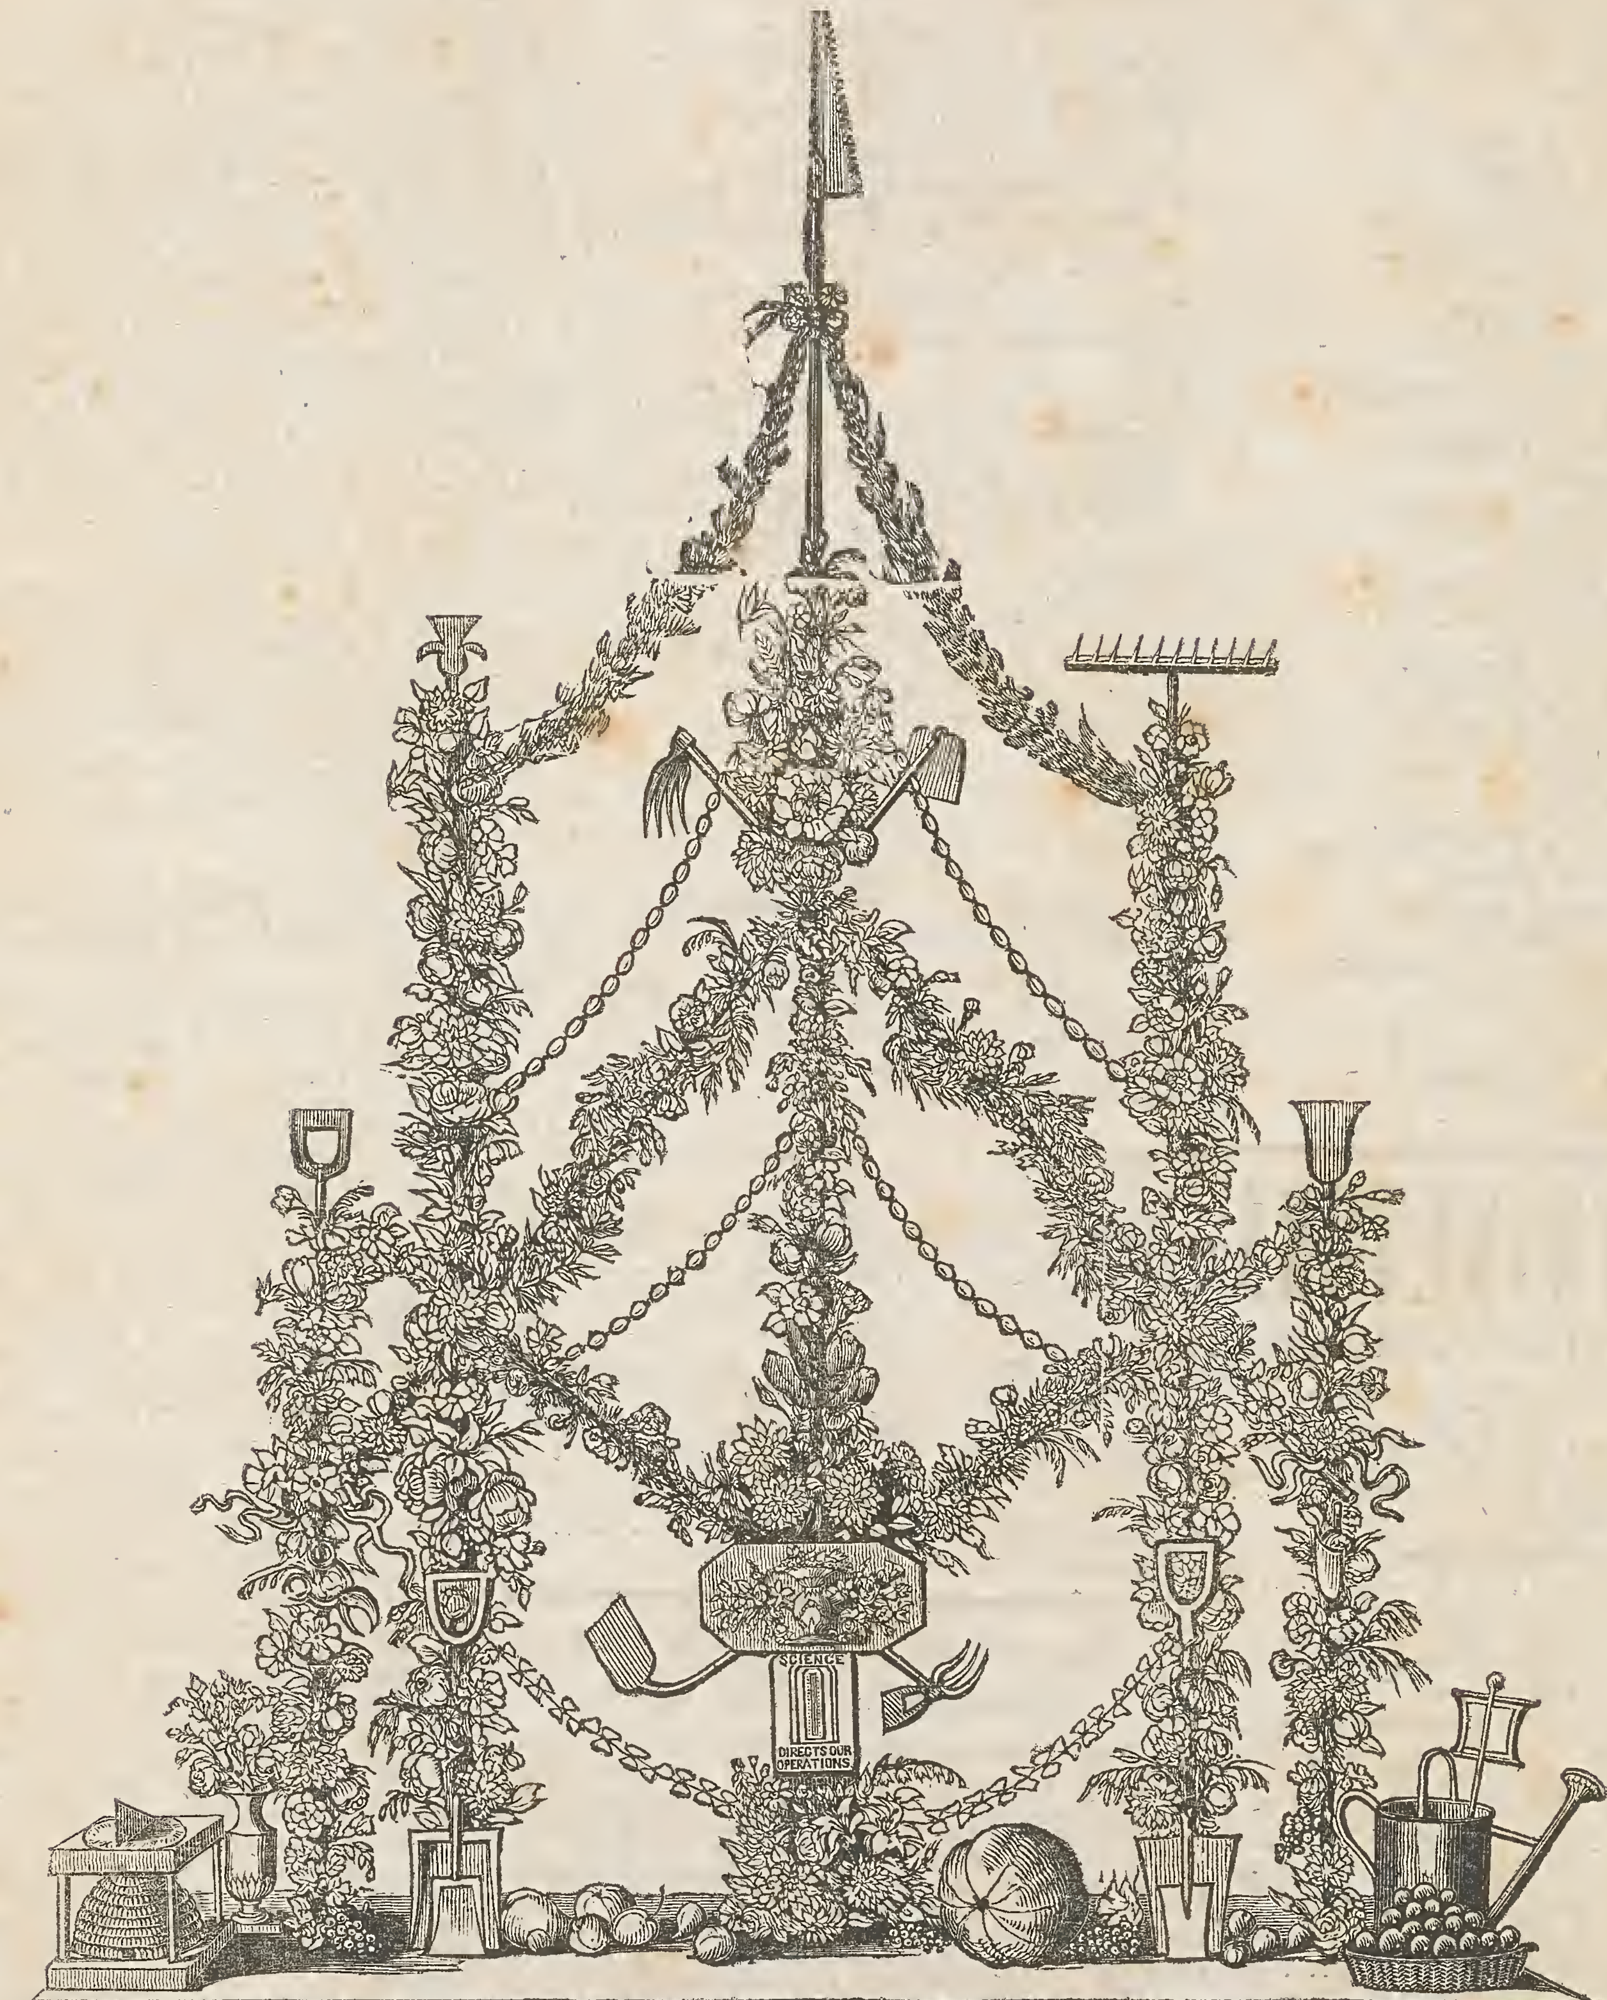
In order to mature the subjects, and ensure the perfect execution of the works, they will be issued in setts of five and ten volumes at a time, which will also accommodate the Trustees in the receipt and disbursement of the funds intended for the purchase of district libraries.

N. B The school trustees, by special provision of law, are to exercise their own choice in the selection of books best suited for their respective district libraries.

☞ Trustees, booksellers, private and public libraries, supplied by the publishers, or at the office of the library, &c., 126 Fulton-street, New-York.

APOLOGY.

We beg leave to apologise to our subscribers for the great delay occasioned in getting our last number. It was on account of the bad roads between this city and New-York, and the slow manner of taking impressions of the portrait accompanying this paper, only about 500 being struck off in a day.



[*For description, see page* 193.]

THE CULTIVATOR:

A MONTHLY PUBLICATION, DEVOTED TO AGRICULTURE.

I KNOW OF NO PURSUIT IN WHICH MORE REAL AND IMPORTANT SERVICES CAN BE RENDERED TO ANY COUNTRY, THAN BY IMPROVING ITS AGRICULTURE.—*Wash.*

VOL. VI. NO. 3, WASHINGTON-ST. ALBANY, N. Y. MARCH, 1839. No. 1.

Conducted by J. BUEL, of Albany.

TERMS.—ONE DOLLAR per annum, to be paid in advance. Subscriptions to commence with a volume.

Special Agents.—L. & R. HILL, Richmond, Va.; BELL & ENTWISLE, Alexandria, D. C.; GIDEON B. SMITH, Baltimore, Md.; JUDAH DOBSON, bookseller, D. LANDREITH, and M. S. POWELL, seedsmen, Philadelphia; ISRAEL POST, bookseller, 88 Bowery, ALEX. SMITH, seedsman, P. WAKEMAN, office of the American Institute, Broadway, N. York; HOVEY & Co. Merchants' Row, Boston; ALEX. WALSH, Lansingburgh, and WM. THORBURN, Albany, gratuitous agents. For general list of agents see No. 12, vol. v.

The Cultivator is subject to common newspaper postage.

☞ The published volumes are for sale at the subscription price, or, if bound, the cost of binding added. The bound volumes may be also had of our Agents in the principal cities.

THE CULTIVATOR.

TO IMPROVE THE SOIL AND THE MIND.

Common School Libraries,

Are now attracting much of the public attention, and we begin to discover the want of suitable books, or a suitable collection of books, for these new establishments, adapted to the capacities and the business of our rural population; for it is generally conceded by intelligent men, that the two collections now offered, to wit, that got up, or recommended, by the American Society for the Diffusion of Useful Knowledge, and endorsed by the late Secretary of State,—and the one offered by the American Sabbath School Union, of Philadelphia, whatever intrinsic merits they may possess as literary or theological collections, are both of them glaringly deficient in what is most essential and most useful to an agricultural population. They contain little or nothing that is calculated to afford instruction, to the great business classes of the country, in their respective employments. The farmer and mechanic, and even the housewife, require *professional* books—books that will instruct them in their several employments—that will render their labors more enlightened, more pleasant, more profitable, more respectable—as much as the lawyer, the physician, or the clergy require professional books, to perfect them in their several vocations.

It is a well-known fact, that our system of farming is, in the main, wretchedly bad; that while many farmers get little more than a bare compensation for their labor, under a constant deterioration of soil, there are others, more enlightened, and who pursue a better system of husbandry, that derive an annual nett income of seven, fourteen, twenty-one, twenty-eight, and even thirty-five dollars, from every acre of land they cultivate. It is also well known, that our poorest farmers—not in means but in management—never buy, and seldom read, any publications that might teach them how to improve their practice.—But were such works placed in a common school library, at the expense of the state, the parents *might*, and the children *would*, read and profit by them.—There was more truth than poetry in the boast of the pedagogue, that he governed the village—because he governed Master Jacky, who controlled his mother, who influenced the father. Parents will listen and respect the reasonable counsels of their children. Were books upon their future business of life placed in common school libraries, the young would read them, as matters of curiosity, if not of instruction—and their minds would become imbued with a mass of useful knowledge—and generally with the ability and disposition to profit by it, which could not fail of producing the best effects on society. Sow the seeds of usefulness in the spring-time of life, and they *will* germinate, they *will* grow, and they *will* give the increase. Teach the young to provide for themselves, and you qualify them to be useful to others. Neglect this first duty, and, so far as your agency extends, you consign them to indigence or to vice. We do not mean to trespass upon credulity when we state it as our belief. that were a good collection of works upon agriculture, the mechanic arts, and rural affairs, placed in every common school library in the country towns, this measure alone would, in ten years, double the products of our soil; and would elevate, in nearly a corresponding ratio, the industrial and moral character of our population.

We cannot omit, in our consideration of this subject, to contrast the wisdom of a sister state, with what we deem the short-sighted policy of our own. The legislators of a state hold the same relation to the population, that parents do to children. They are presumed to be more wise, more provident, and to possess a stronger foresight, than those for whose benefit they act; and the legislator, or the parent, who, from the lack of moral courage, sacrifices the ulterior and substantial welfare of those entrusted to his care, to subserve selfish views, or to acquire temporary applause, abuses his trust, and mistakes alike his duty and his interest.

We have appropriated $55,000 a year, of the public moneys, for one of the noblest objects that ever formed the basis of a legislative appropriation—the diffusion of useful knowledge—the knowledge that enables men to provide better for themselves, to improve their mental and moral powers, and to qualify them to be more useful in life;—to every family—to every individual—be he rich or poor, and be his occupation whatever it may—whether he reside in a splendid mansion or a log hut. Our legislators have virtually said, 'we recognize no distinctions in our republican family. We have made ample provision for them all, for becoming wise, wealthy and distinguished in life. But how have they carried out the plan of dispensing equally these munificent provisions? The mass of our population know as little what is best for their own interest, in regard to a selection for common school libraries, as would our children know what is best for their future welfare in life—because they have not had the opportunity, or the means, of acquiring that knowledge which would render them competent judges. Had the question been left to the ballot-box, the Erie and Champlain canals would never have been made. Their ulterior advantages to the state, could not have been scanned by superficial minds. Had the question been submitted to a popular vote, two millions of the public money would not probably have been appropriated to colleges and academies, for, we may say, the exclusive instruction of the learned and liberal professions—the unproductive classes of society—while the productive classes—the rank and file of our population, were left to their own unassisted exertions, to acquire fortune and fame, and to keep down the aristocratic influence of the thus privileged classes. Yet we do not complain of what *has been done.* We only complain of what *has not been done*—that the public bounty has not been extended alike to ALL—to the producing as well as to the non-producing classes. We should take care, that while we are rearing the splendid column, and embellishing it with architectural beauty, we do not neglect the foundation upon which rests the entire structure. But to return from this digression—

How have we carried out this munificent grant, made for the benefit of our people—our *whole* people?

We have left the expenditure of this money to the trustees of common schools—many of whom cannot probably even read—and forty-nine out of fifty of whom—we speak it without disparagement to their integrity or respectability—our legislators would not entrust to purchase a library for themselves. We have put the public money into their hands, leaving it to their wisdom or their weakness, to decide, whether they shall lay it out in wholesome food or in poison—in useful knowledge or in useless trash—in romance and novels, which vitiate the taste, and unsettle the business habits of life—in the biography of the conquerors of the world, and in the history of foreign lands, with which we have little intercourse, and from which we can learn little that is useful, in arts, in commerce, in politics, or in morals—or in works of substantial utility to our business, our improvement and our happiness.

But suppose these school trustees are all competent to make good selections—that they are all men of sound intelligent minds, acquainted with literature and science, and with modern improvements in the arts of productive labor—let us for a moment look to the *economy* of the matter. An edition of ten thousand copies of any book—and ten thousand is the number of our school districts—can be had for *one-half, or less*, of the retail price of the same work from a book-store. So that ten dollars expended in this way, by the state, would have gone as far in purchasing books, as twenty dollars expended by the trustees in a village or city book-store.

But there is still another difficulty. Suitable books cannot be obtained except in the larger cities, even at this sacrifice. Thus the trustees must either incur the additional expense of procuring them from thence—of foregoing their share of the public bounty—or, sad alternative! of buying such as are not adapted to their wants—perhaps refuse stock, got up, like Pindar's razors, to sell! and as illy adapted as Pindar's razors for the purpose for which they are wanted.

One word as to the utility of books on agriculture and rural economy to *all* classes of society. Is there an individual to whom the perusal of such books may not be useful? Is there a branch of knowledge so generally beneficial to the state as this?—one more susceptible of improvement, or that exerts a more salutary influence upon the habits and morals of our population? To study agriculture, is to study the laws of nature, and their application to the wants and convenience of man.

Let us now turn to our sister Massachusetts.—With the same benevolent design of diffusing useful information among her whole population, that we have manifested, she has made provision for establishing common school libraries. But instead of leaving the selection to trustees, a great many of whom at least must be incompetent to the task, she has chosen some of her most worthy and distinguished citizens to form a board of education; and has added another, perhaps no less distinguished, as the efficient secretary of the board—to this board she has confided the all important charge of providing common school libraries. She means to put in the hands of her children good books, for their instruction and improvement, and on the lowest terms; and to be certain that the books shall be both good and cheap, she selects them herself, as every prudent parent will do, and gets them at wholesale prices.

To carry out the views of the legislature, the board of education in Massachusetts are now employed in making up a common school library, to be principally composed of books expressly written for the purpose, and adapted to the capacities, the wants and the improvements of her whole population. And the more effectually to accomplish this end, the board has enlisted the services of the most talented men of our country—and even of ladies—for ladies may do much to improve household economy, and to give a polish and charm to rural life. Among the writers who have engaged in this work of usefulness, we find the names of distinguished individuals of this state, and of other states of the Union. The library is to consist of one hundred volumes, one-half adapted to the senior and the other half to the junior branch of schools. It is to embrace matters in the various departments of knowledge, so as to improve the condition of all; *and no volume is to be accepted until it is approved by each individual member of the board.*

Comparisons, says the adage, are always invidious; and they are so when introduced for mischievous purposes; but they are certainly commendable when they are made to show us our faults, and to teach us how to correct them. Although it is not fair to draw conclusions before results have developed, we can hardly mistake the tendency of the two modes of proceeding which we have contrasted, nor hesitate in giving a decided preference to the policy which has been adopted in our sister state.

Our Country—our whole Country.

There is no one business of life which so highly conduces to national prosperity and independence, and to general and individual happiness, as the cultivation of the soil. Agriculture may be regarded, says the great Sully, as the breasts from which the state derives its support and nourishment. Agriculture is truly our nursing mother, which nurtures, and gives growth, and wealth, and moral health, and character, to our country. It may be considered the great wheel which moves all the machinery of society; and that whatever gives to this a new impulse or energy, communicates a corresponding impetus to the thousand minor wheels of interest which it propels and regulates. Providence seems wisely to have ordained, that because this is the most necessary employment towards the subsistence and comfort of the human family, its labors shall receive the highest and most substantial reward. While the other classes of society are directly dependant upon agriculture, for a regular and sufficient supply of the means of subsistence, the agriculturist is enabled to supply all the absolute wants of life from his own labors; though he derives most of his pleasures and profits from an interchange of the products of labor with the other classes of society. Agriculture has been called the parent of arts, not only because it was the first art practised by man, but because the other arts are its legitimate offspring, and cannot continue long to exist without it. It is the great business of civilized life, and gives employment to a vast majority of almost every people.

The substantial prosperity of a country is always in the ratio of its agricultural industry and wealth. Commerce and manufactures may give temporary consequence to a state; but these are always a precarious dependence. Venice, Genoa, Portugal, Spain, &c., each in turn rose to wealth and power from commercial enterprize. But they all now exhibit melancholy evidences of fallen greatness.—Their population degenerated under the corrupting influence of commercial wealth, and having no suitable agricultural basis to rest upon, they have fallen in succession, from their high standing, victims to the more robust energies of rival powers, or to the enervating influence of domestic cabals. They exhibit nothing now, in their political or social institutions,—in their agriculture or the condition of their population,—that can be admired or coveted, by the freemen of America. Great Britain has now become ascendant in commerce and manufactures; yet her greatness in these sources of power and opulence, are primarily and principally owing to the excellent state of her agriculture,—without which she could not probably sustain her manufactures or her commerce, in their present flourishing state, or long retain her immense foreign possessions, or any thing like her present population. Only one third of her population are said to be employed in agriculture; yet the labors of this one third, such is the high condition of her husbandry, suffice to feed themselves and the other two thirds. Five millions of agricultural population, of all ages, produce annually, from her limited soil, seven hundred millions dollars worth of agricultural produce, averaging about one hundred and forty dollars to each man, woman and child. The recently published letters of Dr. Humphreys, are so conclusive, and instructive, upon this subject, not only in regard to the importance of agriculture to a nation, but as showing the susceptibility of this art of high improvement and great productiveness, that we subjoin below an extract from one of his letters.

> "It is the opinion of competent judges, that the advances made in the agriculture of Great Britain, during the last seventy or eighty years, are scarcely exceeded by the improvement and extension of its manufactures, within the same period; and that to these advances, no other old settled country furnishes any parallel. That they have been very rapid indeed, the following figures and comparisons abundantly show: In 1760, the total growth of all kinds of grain in England and Wales, was about 120,000,000 bushels. To this should be added, perhaps, 50,000,000 for Scotland—making a great total of 170,000,000. In 1835, the quantity in both kingdoms could not have been less than 340,000,000 bushels. In 1755, the population of the whole island did not much, if any, exceed 7,600,000. In 1831, it had risen to 16,525,180, being an increase of 9,000,000, or 120 per cent.! Now, the improvements in agriculture have more than kept pace with this prodigious increase of demand for its various productions; for it is agreed on all hands, that the 16,500,000, or rather the 17,500,000, (for more than a million has been added since 1831,) are much fuller fed, and on provisions of a far better quality, than the 7,500,000 were, in 1755. Nor is Great Britain indebted at all, at present, to foreign markets for her supplies. Since 1832, she has imported no grain worth méntioning; and till within the last six months, prices have been so exceedingly depressed, as to call forth loud complaints from the whole agricultural interest of the country. England is, at this moment, so far from wanting any of our bread-stuffs, if we had them to export, that she has been supplying us liberally all winter from her own granaries; and, according to the latest advices, she had still bread enough, and to spare. Again, it is estimated by British writers, of high authority, that the subsistence of 9,000,000 people costs, in raw produce, no less than £72,000,000, or £8 per each individual, per annum. According to this estimate, the annual product of this great branch of national industry is $350,000,000 more at present, than it was in 1755; which is more than twice the value of the whole cotton manufacture of the country, in 1831. Now if it costs $350,000,000 to feed the increased population of 9,000,000, then to feed the present population of 17,500,000, must cost near $700,000,000! What an amazing agriculturul product for so small a territory! And yet it is the opinion of practical men of the highest respectability in England, that the raw produce of the island, might be well nigh doubled, without any greater proportional expense being incurred in its production; that is to say, 25,000,000 people might draw their subsistence from one little speck in the ocean! Now *we* have a territory more than fifteen times as large as the island of Great Britain; and what should hinder it, when it comes to be brought under no higher cultivation than some parts of England and Scotland, from sustaining a population of 500 or 600 millions of people? This would give to Virginia something like thirty millions; to Illinois and Missouri ,about the same number each; to New-York near twenty-five millions, and so on in proportion to the other states, I am quite aware that this estimate will be regarded as extremely visionary and incredible, by many of your readers; but not more so than it would have been thought in the middle of the last century, that England, Scotland and Wales, could ever be made to sustain thirty-five or even thirty millions."

A *city* may flourish by foreign commerce—by becoming the carrier of other nations—till foreign aggression, or foreign rivalship, or the opening of new channels of commerce—contingencies of no unfrequent occurrence, shall blast its prospects, and consign it, like Persepolis, Petra, Tyre, and other ancient cities of the east, to ruin and oblivion.

A *town* or *district*, may flourish by manufacturing industry, as many have done in ancient and in modern times, as long as it can exchange its merchandise for the means of subsistence and of acquiring wealth; but if its dependence for these is upon foreign lands, its prosperity is unstable—the interchange is liable to be interrupted by wars, rivalships and other contingencies.

A *country* can be long prosperous, and truly independent, only when it is sustained by agricultural intelligence and agricultural industry. Its foreign commerce may be swept from the ocean; its manufactures may perish; yet still, if its soil is tilled, and well tilled, it can be made to yield all the absolute necessaries of life;—it can, when misfortunes abate, like the roots of the trunkless tree, send forth a new stem, new branches, new foliage and new fruit; it can rear again the edifice of the manufacturer, and spread again the sails of commerce—and it will yet retain the germ and the spirit of independence.

The preceding facts will serve to show the importance of agriculture to a nation, in sustaining its prosperity, and its independence, and in supplying the wants, and multiplying the comforts of its population. The same reasoning that applies to nations, applies to states, to counties, to towns and to neighborhoods. Agriculture constitutes the basis of their prosperity, directly or remotely; and the blessings which it confers are always in the ratio of the intelligence, skill and industry which direct and control its operations. Take a town, for instance, which has a mixed population of the various classes of society. If the average produce of each acre of land is but ten dollars, it is sufficient, merely, to cover expenses and to feed the farmer's family. Having nothing to sell, the farmer of course cannot buy; or, if he buys, he cannot pay, the merchant, the manufacturer or the mechanic, nor can he support the lawyer, the physician, the schoolmaster, or the clergyman. But if every acre is made to produce thirty dollars worth of produce annually, which most lands, properly managed, are capable of doing, the twenty dollars, or two-thirds of the whole product of the soil, become virtually a circulating medium. It is so much surplus wealth, created by the agricultural labor of the town. Now let us suppose, further, that the lands in the town amount to twenty thousand acres. Under the reckless system of management, which too generally prevails, and which upon the average does not produce over ten dollars an acre, in old improved lands, the product would be barely sufficient to maintain the agricultural population, without adding to their wealth, or enabling them to buy of the merchant or others, the necessaries and comforts which they stand in need of. I am aware that this does not hold good in practice; for even the most shiftless farmers do buy; but if they pay, it is at the expense of many of the substantial comforts of life, or perhaps ultimately of their farms, which they might continue to enjoy under a more enlightened system of management. But under the improved system, which we have not graduated high, at thirty dollars per acre, and which is under the average product of well cultivated lands, both in Europe and America, the aggregate agricultural labor of the town, would give an annual increase to its wealth of *four hundred thousand dollars*. Is there an intelligent, reflecting man, who cannot see and appreciate the advantages to society—to the state and to the nation, of a high state of improvement in our agriculture? Is there one who does not see his personal interests promoted by this certain and constant influx of wealth, drawn from the soil—prolific in the bounties and blessings of a wise and beneficent Creator? He has spread every where the means of making man wise and happy. He has given him the capacity to apply these means to his own good. He has commanded him to bring his capacities into constant and active exercise; and He has *promised* to reward, and He will reward, all who prove faithful to the command.

I do not aim to disparage the other great branches of national industry, which are prolific sources of wealth and happiness, by praising agriculture; but I think the importance of this great business to the state, has not been duly appreciated, nor its interests sufficiently regarded and promoted by those who have had the management of our state affairs. My object is merely to make agriculture the base, as it ought to be, of the social superstructure. We are so prone to look *up* for blessings, to what are termed the higher walks of life, and to expect them to fall upon us without an effort, that it becomes necessary, sometimes, to point to their legitimate sources *below*, in the soil. Agriculture, manufactures and commerce are all important, in a public point of view, in the order in which we have named them; and, like the human body and its members, are reciprocal aids to each other. The agriculturist gathers from the soil the elements of usefulness; the manufacturer fits them to our wants; and the merchant becomes the factor of both, and the medium of interchange.

It is but just, in the mean time, to suggest some of the important bearings which our manufactures have upon the prosperity and independence of our country. These consume the surplus products of the soil; they convert into useful fabrics the wool, the hemp, the flax, and much of the cotton, of the farmer and the planter; and they supply to the great agricultural mass of population, articles of necessity and convenience, at a cheaper rate than the farmer could fabricate them for himself. *The manufacturers of our country consume more of the surplus provisions of our soil, than all Europe, Asia and Africa, put together.* I know it is said, that we can get our wearing apparel from Europe, had we no protecting duties, cheaper than we can manufacture it ourselves. And this is undoubtedly true, as regards many articles we use. But what would be the consequence? What was the consequence in 1836, when we were flooded with foreign goods, without the means of paying for them? Our manufacturers became embarrassed; many of the mills were stopped, and a general stagnation of all business ensued. Had the causes which produced that state of things, continued to operate, a complete prostration of our manufacturing energies must have ensued, and the manufacturer been obliged to seek his employment, and his bread, among the agricultural class: the home market for the surplus products of our soil would have been cut off, and the stimuli to industry and enterprise every where paralyzed. Europe does not want, and will not buy, our agricultural products. She sells to us bread stuffs. Ours must find a home market, or no market at all.

But there is another consideration which claims for us an interest in our manufactures. Why are manufactured goods cheaper in Europe, than they are in America? Not because our workmen are less expert, or our machinery less perfect. The difference lies in the social condition of the workmen of the two countries—in the price of labor. So depressed is the condition of the operatives in Europe, that they are compelled to work for a bare living. They enjoy but few political rights. There, the many toil to support the few, in luxury and extravagance. Here the case is different. Our citizens enjoy equal rights, and the spirit of our institutions demands that they should be so rewarded for their labor, as to be able to assert and maintain their rights. Depress them by poverty and want, to the condition of the operatives in European workshops, and you degrade them as men, and render them dangerous as freemen.

The interests of the different classes of society, in our country, are so intimately interwoven, that it may be assumed, as a truth, that each class, and each individual, best subserve their own good, when they endeavor to promote the welfare of all, of every other class and individual. It comes then to this, if our views of the matter are correct, that agriculture, being the great conservative principle of national prosperity, independence and character, should be primarily supported—should be encouraged, enlightened and honored;—that our manufactures, being necessary, like the elaborating organs of the plant, to convert to convenient and useful purposes the products of agriculture, should hold the second rank in our regards—as a branch of national industry, which cannot be dispensed with, without manifest injury to the other classes of society, and without periling our independence as a nation;—and that agriculture and manufactures being duly cherished, commerce, as a necessary medium of interchange between the two great branches of national industry, and between them and foreign nations, will as certainly prosper and flourish as the tree in a rich soil will, which is braced and supported by a good system of roots below, and by a healthy top and foliage above. Let us then improve our agriculture, and foster and protect our manufactures—that our commerce may enlarge its boundaries, and multiply its gains. Then may we, in the spirit of our motto—exclaim—OUR COUNTRY—OUR WHOLE COUNTRY.

Root Culture.

I.—THE POTATO.

Every farmer cultivates the potato, but few farmers cultivate it as profitably as they might. The average crop does not probably exceed one hundred bushels an acre. It may be made to exceed three hundred bushels the acre, and without increasing, materially, the expense of culture. It is a reproach to us, that this root is brought three thousand miles—from England, Ireland and Germany, to supply the wants of our city population. Let us try to do better. It is in the hope that we may contribute to increase our average product, so as to supply the demands of our market, that we give the following directions for its culture.

Soil and preparation.—A mistaken notion prevails with many, that the best potatoes are grown on a warm sandy soil. The reverse of this is true. The best potatoes, as to quality, are believed to be grown in the west of England, Ireland, Nova Scotia, Maine, and other high latitudes, and particularly in humid climates. In a dry season, the quality and quantity are inferior with us, to what they are in a moist and cool one. The potato zone does not extend south of New-York—that is, its quality deteriorates south of that latitude; and it probably has the most congenial climate between 42° and 45°. If these assumptions are well founded, then it should be our aim to plant upon a cool and moist, though not wet soil, which approximates nearest to the temperature of the best potato-growing districts elsewhere. The potato will grow any where, if there is vegetable matter and moisture, but it will be inferior upon dry sands and stiff or wet clays. It does best in loams, or reclaimed swamps; and it pays well for a good dressing of long manure, and should, if practicable, be planted on the first furrow of a grass ley. If the sod is old and tough, plough deep in September, having first spread the manure, if to be had at the time; but if the ley is one of clover, of one or two years old, the ploughing may be postponed till spring. If ploughed in September, without manure, this may be spread upon the ground just before planting, and buried with a light furrow so as not to turn up the vegetable matter of the sod. In our practice of always sowing clover with small grains, we seldom fail of having a tolerable grass ley for the corn and potatoes which are to follow; and its value to the crop doubly compensates for the cost of the clover seed. The potato has a system of roots which strike deep, if the soil will permit, to collect food for the plant. A decomposing sod, with the manure which should accompany it, turned with a deep furrow, affords the best aliment for the plant, and is deposited where the roots naturally seek it, and where it remains cool and moist. The stolens have a different office to perform. They require more air and heat, shoot horizontally, and if buried deep in culture by the plough will protrude a new set near the surface. So that a rich deep soil, having a good sod and a mellow surface, is best adapted to this plant. Harrow thoroughly before planting.

Manures.—The value of manures to the potato crop was illustrated in the preliminary remarks in our last number; and indeed a large crop is seldom obtained without this auxiliary. Long or unfermented manure is preferable to that which is rotten. And remember, this manure does not become more impaired in value for the crop which is to follow the potatoes, than if it were summer-yarded. We prefer applying it broad-cast, with an unsparing hand, previous to the last ploughing; and we approve of Mr. French's practice, of sowing plaster upon the manure, instead of afterwards applying it to the growing plants.

Seed.—A thousand and one experiments have been made, and with various results, to determine the relative value of large, medium or small seed—of cut or whole tubers. We think the majority of these experiments is in favor of medium, or a little more than medium sized roots, for seed, cut into sets of two or three eyes. On the principle that like produces like, such a seed will produce a crop of the most desirable size for the table. Each eye forms a distinct plant, like a kernel of corn, and the size of the tuber, and not of the set which is taken from it, will give character to the product. If the variety has a dwarf habit of growth, more sets may be put in a hill, or they may be planted nearer in the drill, than where the growth is tall, or where the tops send out many lateral shoots. Rich ground will also sustain a greater number of plants than poor ground. The Rohan, and we are told also the forty-fold, require thin planting. The object should be to give the plants a good pasture, and not to have the tops so thick as to exclude the solar rays from the soil.

To produce early potatoes, or to bring a crop to early maturity, it is advised to gather the seed before it has attained maturity, to expose it some days to the influence of the sun, and to select the top ends for the earlier crop. We have a strong illustration of the correctness of these conclusions, in Loudon's Gardeners' Magazine. A correspondent of that journal made the following experiment: He dug every other row of a potato patch for seed while the vines were fresh, and exposed them in the sun until they had become green. In February, he cut them crosswise, leaving the bottom and top in separate sets. He cut those which had been suffered to ripen in a similar manner, and planted the four kinds in alternate rows. They were all planted on stable litter, and covered with about three inches of earth. A part of each kind received no subsequent earthing. We give the result in the writer's own words.

> "The early potatoes not earthed up, grew close around the stock or stem, like eggs in a nest, and so near the ground that they might be picked off with the finger, leaving the stock or stem uninjured, to produce more potatoes from the runners. From the eye sets of the unripe tubers, we had a supply every day for a fortnight; when those of the bottom sets came into use for another fortnight; at that time potatoes from the eye or top sets from the ripe seed came into use, and were succeeded by potatoes from the bottom sets of the ripe seed.—Those kept for seed, or the table, were earthed up as usual, and each row produced almost as large a crop as any two rows not earthed up—the luxury of an early potato being a greater object than the quantity."

Choice of sorts.—There is a difference of nearly one-half in the nutricious or fattening properties of different varieties of the potato. Those which are best for table are best for market, and best for farm stock, though their yield is generally less than that of the coarser varieties. Those in the highest esteem are the Pink-eyes, Mercers, Sault St. Marie, St Helena; and almost every district has its other favorites. The Rohan, we think, will ultimately obtain the ascendancy, on account of economy in seed, its yield, and its intrinsic merits.

Mode of planting.—Three modes are practised; in hills and in drills, as a distinctive crop, and in alternate double or threble rows with Indian corn. The propriety of planting in hills or drills depends upon the condition of the soil; if it has been thoroughly subdued by the plough, drills are to be preferred, as they are cultivated with the least expense and generally give the largest product, though they in general demand the most labor in gathering the crop. The practice of raising potatoes with corn, by alternating two or three rows of each, has been eminently successful, where it has been conducted with spirit: the product of the mixed crop has been greater than where each has had a separate department of the field. We omit to notice the Irish mode of planting in beds, as involving an economy in land which we do not require, and an expenditure of labor which we cannot afford. The seed should not be buried more than three or four inches —and the covering should be least in wet ground.

Culture.—The culture of the potato, to be profitable, should be almost wholly performed with the plough, cultivator and harrow—little other labor being required with the hand hoe, than may be barely sufficient to destroy the weeds which these implements do not reach. In the first place, the seed may be covered with the plough, whether in hills or in drills. In the next place, the harrow should be used, before the plants are above ground, to reduce the ridges made by the plough in planting, to pulverize the surface, and to destroy the young weeds. In the third place, the cultivator, or the plough, turning a superficial furrow *from* the plants, may be introduced, when they are not more than six inches above the surface. In the fourth place, the plough may be used to turn a light furrow *to* the plants so as to give their stems an earthing of three or four inches; but the plough should run twice nearly in the same track, that the ridges upon which the crop grows may be rather flat and broad than pointed—rather concave than convex—calculated rather to retain, than to throw off water. Here the hand hoe may be of use in gathering around the stems a portion of the earth raised by the plough, in destroying weeds among the plants, and in perfecting the earthing or hilling process; for the crop should receive no further earthing after the plants are in blossom, when the stolens have shot forth, and the tubers began to form. Earthing after this time causes a new set of stolens near the surface, and a growth of a new set of tubers, which in a measure rob the original ones of their food. We have seen, by the experiments quoted, in raising early potatoes, that the natural place for throwing out stolens, or roots which produce the tubers, is the point of the stem which first comes to the light and atmosphere; that if this point is covered in due time with two or three inches of mould, stolens are protruded into it, which produce the potato; but that if this earth is wanting, the stolens cannot protrude, but that the potatoes grow at the surface, around the stem. After the earthing process described, no further care is required, than to destroy weeds, which may be done with the hoe, or, if long omitted, by the hand.

In harvesting the crop, although we have made much progress in improvement, much remains to be done. The hoe, the dung-fork, the spade, the potato hook, and the plough, followed by the harrow, have each their several advocates. From our experience, we should choose the last first, and the first last, where the crop is in drills; and we should prefer the hook where it is in hills. With the potato hook, when the crop has been in hills, we have thrown out 14 bushels of pink-eyes in an hour, and 27 bushels of the Rohan, though in neither case, did we gather the potatoes—but in both cases, the digging process was thoroughly done. Lawson & Son's potato lifter, figured and described in the August number of our last volume, very much on the model of one before introduced by Capt. Joab Center, seems to be calculated to abridge the harvest labor of this crop. But of this we hope to be able to speak more understandingly another year.

Sorting the crop.—This is an economical process, though little attended to, and may be more profitably done before the crop is housed, or pitted, than afterwards. There is a portion of the crop, often a fourth or a third, which is small, and unfit for the table, for market, or for seed, but which is as good as the large size for farm stock, and which can be economically used for this purpose, in fattening hogs and beef cattle, in autumn and winter. If they are separated at the harvest, they are always in readiness; if not, the sorting is tedious, or is neglected, and the small potatoes are the last that remain, either for the table or for seed. With us the work is a trifling affair. We have a wire sieve, or riddle, the meshes of which are of a size to admit those of a given size, appropriated to swine or cattle, to pass through. As the crop is brought home, a peck is thrown into this riddle, and by shaking it half a minute, the sorting is completed.

Wintering the crop.—The best mode of preserving potatoes in perfection through the winter, is to bury them in shallow pits, in a dry and porous soil—a side hill is the best—where they will be free from water, and to cover them first with straw, and then with earth, and if convenient, coarse manure over the earth, so that they shall be secure from frost. When put in pit or cellar, they should be dry, that is, free from external moisture. Potatoes put into the cellar should be kept as cool as possible without freezing, and air should be excluded by a light covering of mould or sand. A dry warm atmosphere will speedily impair their good properties.

In using potatoes, they are improved by boiling, especially for pigs. The potato belongs to a family of poisonous plants, the *solanum;* the boiling or steaming of which is believed to expel the deleterious, and to improve its nutricious properties. To neat cattle and horses they may be fed raw with manifest advantage. In cooking them for the table, it is preferable to do it by steam. The mode of doinfi it is simple. Get a piece of sheet iron of the size of the bilge of your pot or kettle, perforate it with half inch holes, then clip off two parallel sides so as to admit it into the mouth of the vessel; put it in; put some water *under*, and some potatoes *over*, this perforated iron; and when the water boils, the potatoes will be steamed and prepared for the table: or, if to be boiled, put them in the vessel while the water is cold, that they may heat through as the temperature of the liquid increases—that the inside may cook as well as the outside—and when they are near being done, turn off the water, remove the cover, and leave them to dry over a moderate heat.

We will close this article, already longer than we intended it should be, by giving the culture, expense, product and estimated profit, of two crops raised by ourselves, in different years, upon the Albany barrens, the soil a sand loam.

Culture.—The field was in clover. We applied twenty-five loads of long manure, in May, to an acre, and dropped it at suitable distances for spreading; marked out two lands of equal breadth, twenty feet; and having the seed prepared, proceeded to planting, which occupied three men, a boy and team three half days. One man took charge of the team; a second raked the manure into the furrow, and trod it down as he went on; and a third spread the manure, and with the boy dropped the seed. The rake followed the first furrow, and the manure from two and a half feet surface was drawn into it, and the sets, or seed, dropped at eight inches distance on the manure. The plough followed and turned three furrows, or made three bouts. In the mean time the manure and seed were deposited in the first furrow of the second land, to which the plough followed, and in this way they alternated till the planting was completed. The ground was then rolled, harrowed as the plants began to break the surface, and subsequently ploughed between the rows, and hand hoed once. About half the field was a dry sand knoll, which suffered severely from drought; and the crop here was but a little more than fifty per cent of the other half. The product was ascertained by the agricultural committee, and the product stated embraced the average of the entire acre.

EXPENSE OF EXPERIMENT I.

Man and team 1½ days, ploughing in seed,	$2 00
Two men and boy planting same,	2 00
25 loads manure, at 75 cents,	18 75
25 bushels seed, at 50 cents,	12 50
Rolling, harrowing and ploughing,	1 00
Hand hoeing once,	1 50
15 days taking up crop, (a long time,)	11 25
Rent,	5 00
	$54 00

PRODUCT.

359 bushels large potatoes, at 50 cents,	$179 50	
71 do small, at 12½ cents,	8 88	
		$188 38
Deduct charges,		54 00
Nett profits in experiment 1,		$134 62
At 2s. a bushel the nett profit would have been		$45 25

EXPERIMENT II.

Culture.—This crop had been preceded by wheat. It had 25 loads of long manure, spread and ploughed in. The ground was then harrowed, furrowed or listed with two and a half feet intervals, the seed dropped at eight inches, covered with a plough, a furrow on each side, and the ridgelets rolled. The after culture consisted of two horse and hand hoeings. The crop was harvested with the plough and potato hooks. The product was determined by the agricultural committee:

EXPENSE.

One ploughing,	$2 00
25 loads manure, at 75 cents,	18 75
25 bushels seed, at 50 cents,	15 50
Harrowing, furrowing, rolling and horse hoeing,	3 00
Planting and covering, 3 days,	2 25
Hand hoeing, 2 days,	1 50
Taking up crop,	9 00
Rent,	5 00
	$53 90

PRODUCT.

333 bush. merchantable potatoes, at 50 cts.	$191 50	
77 do small do. at 12½ cents,	9 62½	
		$201 12½
Deduct charges,		53 90
Nett profits,		$147 22½
At 25 cents per bushel, the profit would have been about		$52 00

In these estimates, the whole manure is charged to the crops. Deducting one-half, as is customary, the profits would have been $9.37½ more in each experiment.

Maple Sugar.

We often neglect to profit by things within our reach, and are constant in our eagerness to grasp those which are remote and doubtful. This is particularly the case in regard to our sugar giving maple. We have perhaps enough of this species of tree in our state, to furnish our whole population with sugar, were the business properly husbanded; and if not enough, they might be sufficiently multiplied in time to serve the next generation. The sugar which this tree yields is as good, or may be made as good, as that which comes to us from Louisiana, or the West Indies, and by simple means, available to every sugar boiler—the means which give to sugar the character of white Havana.

As there is much of this article badly manufactured,—and as its value may readily be doubled, and its quantity greatly increased—to aid in these desirable ends, we shall here state the whole process of manufacture, as given to us by a gentleman long practised in the business, and who makes three thousand pounds a year, equal, he says, to any that can be produced from the cane or beet.

He first procures sap buckets equal to the number of trees he intends to tap, which are of course always kept in a cleanly condition. These are perforated with a hole near the upper part of a stave, large enough to admit freely the head of a large nail, upon which they are to be hung, and which nail is to be firmly driven into the tree, near where it is to be tapped, and which may be at any height within reach. The tree is bored, the quill or tube to conduct the sap into the bucket inserted, and the bucket hung upon the nail, and in contact with the tree, to catch the sap. This completes the first process. The second is to gather the sap to the boiling house. To do this in a cleanly manner, butts or large casks are placed upon a sled, with coarse linen strainers tied over the tops, leaving the centre of the strainers to sag so far into the casks as to form a basin large enough to hold a pailful of sap.—This sled is drawn through the sap orchard, the sap gathered and turned upon the strainer, and then deposited in the sap reservoir, near the boiling pans. The strainers keep the sap in the casks, and keep leaves and other foreign matters out of them. This completes the second process. The third is the boiling process. For this purpose, broad sheet iron pans are employed, not more than twelve inches deep, both because they give the greatest surface to the fire, and the greatest to the air, and consequently accelerate most the evaporating process. The sap reservoir, or cistern, is placed so high, that tubes from it conduct the sap directly into the pans, so that when the boiling is started, these are opened, and the pans receive a constant and regular supply. The fourth process, that of clarifying the syrup, and the fifth, sugaring off, we did not particularly learn, and inferred that there was nothing particularly in them differing from the common modes of practice. The next and last process, claying, is the most important. To perform this, a bored log, resembling a pump log, is placed nearly horizontal, one end inclining towards a tub or barrel, to catch the molasses; holes are made on the upper side of the log, and to the centre bore, to admit moulds, of the shape of a sugar loaf, the lower or smaller ends of which being temporarily stopped, the sugar, after it has granulated, is put into the moulds, the latter set in the bored log, and a coat of the best Amboy clay, reduced to a paste, is then spread over the sugar, in each mould, to the thickness of an inch or more, and the plugs drawn from the bottom of the moulds. The water in the clay percolates through the sugar, carrying with it the colouring matter and molasses, falls into the bored log, and passes off into the tub or cask. If the first claying does not suffice to render the sugar sufficiently white, when it becomes dry it is taken off, and a second is applied, when the process is completed.

This is the mode of producing clayed sugar in Cuba, where the clay is sometimes thrice repeated; and it seems to be the mode now adopted in France with beet sugar; and a recent improvement consists in refining it without removing it from the moulds, by the aid of heat and pressure.

We have obtained from the gentleman, whose process of making sugar we have been describing, the following description of his

SAP BOILERS AND MODE OF SETTING THEM.

The best vessel to boil sap in, to reduce the same to syrup, is made of Russia sheet iron; and its size may be in proportion to the quantity to be boiled. The sap of a thousand trees may be easily evaporated in an apparatus such as I will describe.

Make of Russia sheet iron, a pan about six feet long and four feet wide, with sides at right angles, of the same material—six inches high. Also another pan of the same material and construction, but ten feet long and four feet wide.

Erect an arch of free stone or brick, with grates to lay the wood upon, and a good iron door to give a draught, so that the air passing into the arch shall be heated before it touches the bottom of the pan. The plan of the distillery arch will give the idea perfectly, but this is not near as expensive. Set the small pan nearest to the mouth of the arch—say within two feet of it. Let the sides of the pan rest on the sides of the arch about four inches, and at the ends and middle let it rest on three good bars of iron, to prevent its sagging. Let these bars be chamfered on the front edge, so as not to catch the wood as it is carelessly thrown into the arch, and let them be long enough so as to protrude over the arch on both sides, and be bent over at the ends, so as to prevent the arch from spreading, and the bars from sagging when heated.

At the farther extremity of the arch set the larger pan, as you have set the smaller one, only let the arch be raised about six inches higher, so that the bottom of the larger pan may be a little higher than the top of the smaller. Set this pan a little dipping towards the smaller, and in the lower end, and close to the boiler, insert a small stop cock. Let the chimney of the arch be immediately beyond the further end of this last mentioned pan. The mason will of course know how to construct the arch, so as to have a good draught. It is desirable to set the arch near to some bluff, so that the sap, when collected in a reservoir, may flow directly into the upper or larger pan.

Both pans are then filled with sap, and fire is put under; and afterwards the sap is only let into the upper pan, and from that into the lower, through the stop-cock above described. In this manner, the lower pan is fed constantly with hot sap, and is constantly boiling.

You syrup down only in the lower pan, and you do not sugar off in either.

You cannot make these pans boil over, and when syruping down, cannot burn the sap, as in the cauldron or pot ash kettle. The wood should be collected and prepared the season before, and kept dry.

As the correspondent, at whose particular instance the above is furnished, may wish to employ kettles instead of pans, we will add, that the great point to be obtained, in constructing an arch, or furnace, is to expose the greatest possible surface of the boiler to the immediate action of the fire. To effect this, two rules are to be observed—first, to conform the brick work to the shape of the boiler, leaving an interval of four or five inches only between them, and to suspend the boiler by the flange resting upon a course of brick set edgeways. Second, to elevate the grate for the wood—an ash pit being left under it—three to six inches above the bottom of the boiler—so that the flame will surround and cling to the boiler on its way to the chimney—and not pass under the bottom and only upon one of its sides.

Litter your Cattle Yards.

Every farmer has, or ought to have, from the produce of his farm, quantities of straw, corn stalks, and other coarse vegetable matters, which the cattle reject, but which is yet good and profitable food for his farm crops, if properly husbanded and judiciously applied. In a well constructed yard, calculated to retain the urine of animals and other liquids, the coarse litter should be spread at intervals through the winter. It thereby becomes doubly enriching to the soil, when spread upon it, by the fertilizing properties of the liquids which it there imbibes. Arthur Young understood the economy of enriching lands, as well as of fattening cattle. He says, if litter is scarce, two tons may be made to suffice for a fattening beast during the winter months; though if plenty, or in situations where litter can be *purchased*, he thinks an animal may convert much more into rich manure. The Flemings count upon the urine of their farm stock as nearly equal to the other excrementitious matter, and they save and apply it with care. We almost wholly lose those fertilizing matters, yet we can mostly save them in concave cattle yards, if we will frequently apply litter to absorb and take them up. He that wastes or sells his litter, is a bad economist, unless he brings from market a return load of dung. The man who rides a load of straw ten miles to market, barely gets pay for his time, while he robs his soil of that which would increase its products. Straw, manufactured into dung by the farm stock, is worth more in the soil than it is in the market, even were the expense of transportation in both cases alike. But it is the waste, or a want of the due application of litter, that is most to be complained of. Let it be remembered, that every vegetable substance, however worthless it may seem, is convertible, if buried in the soil, into corn, roots, hay and pulse, and ultimately into meat, cheese, butter, wool, &c., and that he who would realise the interest must deposit the principal.

To illustrate more forcibly the value of straw and other litter, in augmenting manure, we quote the following from the Farmer's Calendar.

"Mr. Moody—Forty-five fat oxen, in fatting, littered with twenty wagon loads of stubble, raised two hundred loads, each three tons, of rotten dung, worth 7s. 6d. ($1.65) a load.

"Every load of hay and litter given to beasts fatting on oil-cake, yield seven loads of dung, each one ton and a half, exclusive of the weight of the cake.

"Mr. Arbuthnot, one hundred and thirty-four sheep and thirty lambs, penned six weeks in a standing fold, and littered with five loads and forty trusses of straw, made twenty-eight large loads of dung." The straw, at 20s., cost £5.15. The dung was worth £10. Profit £4.5. ($19.20.)

"William White—Thirty-six cows and four horses tied up; ate fifty tons of hay, and had twenty acres of straw for litter: they made two hundred loads of dung, in rotten order for the land."

Messrs. Moody and Abuthnot say it answers well to buy litter with a view to dung; that in feeding oxen with oil cake, one load of straw makes seven loads of dung, each a ton and a half; and that in feeding sheep with turnips, one load made more than 4½ large loads, worth 7s. 6d. each. Mr. White, with 30 loads of straw, made 200 of manure in littering cows, which is 6⅔ of manure for one of straw.

"I have found," says Mr. Young, "by experiments very carefully made, that a ton of straw used in littering a stable kept dry, and the urine not retained, will give three and a half to four tons of dung; but used in littering fat hogs, a ton gave seven or eight of dung."

Our Premiums.

After we had awarded our premiums for 1838, and the sheet containing the award, had been struck off, (Jan. 15,) we received the two applications for the Indian corn premium, which appear in our paper of to-day. Under these circumstances, the last applicants must be content with the reflection, that they have set good examples in farming, have obtained profitable crops, and have *deserved* premiums; and, as we intend to offer other premiums for the coming year, we hope they may yet do better, and put in their claims *in time.*

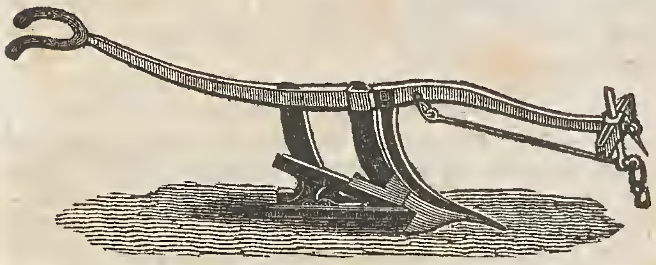
We also received, *in time*, a drawing and description of a farm dwelling-house. The drawing was mislaid, but has since been replaced. This communication contains no estimate of the expense—a material point to one who may wish to adopt the model—as every man should count the cost before he begins to build. We beg our correspondent to supply the deficiency. We have also received, (in Feb.) three other plans and descriptions of farm houses. We intend to publish all these communications, in some one of our future numbers, with the drawings which accompany them; and to prolong the time for competing for the twenty dollar premium offered for the best plan, to January, 1840. In the mean time, we ask such of our correspondents as have not done it, to send us estimates of the cost of materials—wood, brick or stone—for buildings like those they have severally described.

Whitington Spring Wheat.

We noticed the receipt of a sample of this beautiful grain in our January number. Mr. George C. Thorburn, of New-York, has just received a few bushels from England, which he sells at $8 per bushel.

Smith's Subsoil Plough.

[Fig. No. 1.]



The objects sought to be obtained by the use of the subsoil plough, are these, viz:

1. To permit the surplus water to pass down.
2. To render the subsoil permeable to the enriching influence of the atmosphere—to those chemical changes which take place in a fallow; and ultimately to deepen the super-soil, and thereby increase the pasture for the plants growing upon it.

A superficial soil, upon a tenacious subsoil, is often cold, inert and precarious, by reason of the water which settles upon the latter, stagnates in summer, and becomes prejudicial to healthy vegetation. By deepening the permeable stratum from six to twelve inches, with the subsoil plough, the surplus water settles down that much lower, and often beyond the reach of the roots of the crop, and the soil becomes correspondingly better fitted to sustain a healthy vegetation. Crops will not do well where the roots penetrate a stratum abounding in water.

The atmosphere is always charged with the food of plants, in a gaseous form; and the subsoil contains more or less of the elements of this food, insoluble or useless, from the presence of too much water, and the want of atmospheric and solar influence to render it soluble, and fitted for the absorbent vessels of the plant. The subsoil plough not only frees it from excess of moisture, but renders it pervious to atmospheric and solar influence—not only converts the insoluble into soluble food, but adds to it the fertilizing properties of the atmosphere.

By the operations of the subsoil plough, in a few years, the loosened subsoil acquires the fertility of the super-soil, and becomes blended with it; the tilth, the pasture of plants, is deepened and enlarged; the roots have a wider range; the soil will support a heavier crop, and the danger from drought as well as from heavy rains, is materially lessened.

The advantages which have resulted from the use of Smith's plough, were sometime ago noticed in the Cultivator. Its reputation for usefulness has not since been impaired. At the Northumberland cattle show, in October, Mr. Gray, in the course of his remarks at the dinner table, stated, that his attention had been called, a few days before, to a field of wheat, one half of which had been ploughed with a subsoil plough, and the other half by the common plough. "Both of the divisions of the field," said Mr. Gray, "were equally fallowed and manured, and there was indeed, no difference between them, except as to the mode of ploughing. He had carefully examined the results, and had no hesitation in saying, that the half which had been submitted to the operation of the subsoil plough, had produced a crop full one third more than the other half; and many persons who had compared the respective crops, gave it as their opinion, that the produce had been doubled by the use of the implement in question. The diminished produce on the latter part of the field, was occasioned by the water settling in the furrows, and damaging or rotting the stocks, an injury which is obviated by the use of the subsoil plough. In the part worked with this no distinction was observed in the crop between the ridges and the furrows, but every part bore an abundant crop of fine wheat."

It is not to be understood, however, that the subsoil plough is to supersede underdraining in all cases.

Clover—Its Value for Cattle, for Seed and for the Soil.

We have received a communication from Mr. Henry Brewer, of Enfield, Tompkins, illustrating strongly the value of clover, as a means of keeping up the fertility of his land, and of rendering its culture profitable. Mr. Brewer was from old Dutchess, the land of clover. He purchased his farm in Enfield, in 1830, at $8.50 per acre. It now gives a product of from fifteen to forty dollars per acre per annum; and the improvement and the profit he ascribes principally to the cultivation of clover. As the communication is very lengthy, and having the writer's permission so to do, we give the purport of it in a condensed form.

Mr. Brewer remarks, that New-York farmers pay to those of New Jersey and Pennsylvania, annually, many thousand dollars for clover seed, which they might raise for themselves with profit. He would as soon think of buying his seed oats and seed wheat, as his clover seed. He prefers the southern or dwarf clover, because it is fit to cut five or ten days earlier than the tall growing or northern kind, and is more certain of ripening the seed of the second crop. He sows with his small grain, at the rate of fifteen lbs. the acre, and sometimes sows his corn fields after the last hoeing.

Mr. Brewer appropriates his clover to three very valuable purposes—to feed his stock, to fertilize his land, and to fill his purse—and he has succeeded admirably in them all, so far as we can judge. His cattle thrive upon it both as a green and a dry crop—in summer and winter;—his wheat and corn feed and thrive upon it, when buried and decomposing in the soil;—and his purse increases with the increase of his cattle and his crops. And finally, besides feeding his cattle, and fertilizing his soil, the seed of his second crop gives him an acreable profit, annually, of from fifteen to fifty dollars. Now there is no secret in the business—no patent right. He gives you his whole process, that you may profit by his example if you will. We will endeavor to give it in concise and plain terms.

Clover is either used for hay or pasture the first crop, and uniformly for seed and forage the second crop. If for pasture, he turns upon it his stock about the first of May, or when the soil has become so firm that the feet of the cattle will not poach the sod. At this time, the growth is such, as to enable the cattle to thrive. He pastures till about the 20th June, and the closer it is cropped at this time, the better, he thinks. The cattle are then withdrawn, and the second crop is permitted to grow and mature its seed. If the first crop is designed for hay, it is cut from the 20th to the 25th June, although it may not have passed the bloom, or arrived at that state when most farmers deem it in a proper condition to cut. It is important to cut it as early as the 25th, Mr. B. thinks, in order to give the second crop time to grow and mature its seed before it is injured by the frosts of autumn—five days often making a material difference in the seed crop. We do not like Mr. B's mode of curing this early cut clover: he takes it, when partially cured, to his barn, and spreads it about upon scaffolds and poles, till made, and then puts it into his bay. This causes unnecessary labor. Cured in grass cocks, according to our repeated directions, it will be as good as when spread over a barn, and more than half the labor will be saved. Mr. B. thinks clover hay made in the shade is much better than that which is made in the sun. "The next way of curing this green clover," says the writer, "is with wheat straw, that has been kept in the barn for that purpose, by laying a course of hay and then of straw, and so on, until you have it all secured." The importance of mowing the first crop early, is illustrated by the fact, that one of Mr. B's neighbors, who had been persuaded to cut his first crop some days earlier than usual, acknowledged that he should obtain last season, thirty bushels more clover seed than usual, in consequence of it.

The seed crop is gathered with care, and brought to the barn as soon as it is fit, that rain upon it, or unnecessary exposure to the weather, may be avoided, both of which materially impair the value of the buts or straw for fodder. The heads are separated with a flail, and the seed extracted by Robert Rittenhouse & Co's. patent clover machine. The average product in seed, is four to five bushels the acre; which, at present prices, is worth sixty to seventy dollars—a tolerable acreable profit for a second crop. In regard to his clover machine, Mr. B. has cleaned four hundred bushels of seed with his, without a dollar of expense in repairs. It is portable; and "when there is once a machine in a neighborhood," says Mr. B. "I think the farmers will then raise their own seed, as is the case in my neighborhood. And if they raise it themselves they think it costs nothing; they then sow liberally, and get a bountiful return." The clover machine costs sixty dollars, and it would verily seem to be worth more than that amount annually to the farmers of the neighborhood. Mr. Brewer's machine was made by Blackwell, of Albion, Orleans county.

In regard to the value of clover in keeping up the fertility of the farm, Mr. Brewer considers it of the first consequence; for, says he, "I think I can manure my farm with clover, cheaper than I can cart out my manure from my own barn yard; although I have it all carted out in the spring of the year for my hoed crops, while unfermented, because I think it of more value to have it rot in the soil than in the farm yard. I do'nt wish to have it understood that I am an advocate of the miserable practice of leaving my manure in my barn yard, as many of my neighboring farmers do, to waste one half of its best qualities, for I have it thoroughly cleaned every year."

One word as to the condition of the farm when it came under Mr. B's management. The soil is described as a sandy loam, mixed with slate gravel, and most of it very stony. When he came on to it in 1830, "there was about fifty acres of cleared land, and it was considered one of the poorest farms in the town, by my neighbors, who assured me I could not get grass enough from the farm to keep one cow. There was but two acres of meadow upon it, and that was too wet to plough. But this did not discourage me. I purchased two and a half bushels of clover seed the first spring, which some of my neighbors thought was enough to seed my whole farm, weeds and all; but I sowed it on sixteen acres." Such was Mr. Brewer's beginning; and the reader is already advised that this spirited beginning has been followed up for eight years with increasing advantage. The wheat crop has averaged from eighteen to twenty-four bushels per acre.

An Agricultural Society in Montgomery.

A society is organizing in Montgomery, under the style of "*Agricultural and Rural Society*," calculated to produce the best results, and to benefit every class and age of the population. Every town is expected to organize an auxiliary society, the president of which is a vice-president of the county society; and the school districts constitute in a measure departments or branches of the town societies. The plan embraces—

"1. Whatever regards health and domestic comfort—and includes a provident care of all domestic animals.

2. An improvement in the breeds of farm stock, and a better provision for their maintenance and comfort.

3. An improvement in garden culture, orcharding and rural embellishment.

4. Improvement in common roads,—an improvement much wanted every where among us. And as a sure and solid foundation to the whole,

5. *Common Schools*—On the improvement and success of these, perhaps all else depends. There must be introduced agreeable manners and systems of education, to invite and allure children to useful action. Right education developes and directs powers of mind and body, where energies might otherwise slumber, or do mischief for life. It forms and fixes individual, social, and national character. There must be provided competent teachers, and geometrical forms and figures of surface and solids; mechanical, mathematical and philosophical instruments and apparatus, and correct engravings and colourings to explain the general anatomy and economy of animals and vegetables; collections of plants and minerals. Books, composed and compiled, suited to the intelligence and condition of children; few such are to be found, and perhaps none, exactly fitting for American education. Adequate teachers are almost equally rare. Children themselves, and parents, and the friends of education, liberty, morals and religion, may do much, yet the co-operation of the legislature is demanded in a plan so desirable, so general and evidently so practicable."

Cuts of Farm Implements.

We have received several drawings of new farm implements and machinery, to be inserted in the Cultivator. The rule we have adopted in regard to these is this. If the implement is patented, the right of using it is private property, and the patentee, or proprietor, must be at the expense of the cut, if one is to be inserted. If there is no patent right, and every one has a right to make and use it, we are at the expense of the cut, if we deem the implement one of manifest public utility. This rule has only been departed from when we have been presented with the new implement, and have been satisfied, upon trial, of its usefulness.

Patent Office.

It appears from the annual report of the commissioner, that 520 patents have been issued during the last year; that 224 patents have expired; that the receipts of the office have been $42,123.54, and the ordinary expenses of the office have been $19,180.18—leaving a surplus of $19,243.36.

Farmers' Garden.

PERENNIALS, BIENNIALS AND ANNUALS.

Perennials do not generally flower the first year, but die down to the ground, and spring up again the next spring, for a number of years—as peonies, lillies, &c. *Biennials* flower the second year and then die. *Annuals* flower and die the year they are sown. We shall omit the botanic names, and notice such as are most conspicuous for beauty and fragrance, and are of easy culture.

1. *Amaranthus,* the globe and the tricolour, the first admired for its everlasting flowers, and the latter for its foliage. Plant the seed in May, and allow the plants room to spread. Annual.

2. *Aster,* (China) An annual. The double, or quilled and the German, or striped flowered, are most admired, though a bed of the early flowering, exhibiting as they do a great variety of colours, is highly ornamental. Sow early. If a small space in the hot bed can be given to this, the amaranthus, balsam, &c. their season of flowering may be greatly accelerated.

3. *Balsams,* a beautiful annual, of infinite varieties, very much improved within a few years, in brilliancy and in combination of colours. One of the most showy flowers for the autumnal borders. Gather seeds before the pods change colour, and sow early.

4. *Canterbury Bell,* biennial, admired for the profusion of its large bell-shaped blue and white flowers.

5. *Chrysanthemum,* perennial, much admired, of many varieties, propagated by dividing the roots. South of New-York they generally flower well in the open ground; but in our borean region, they must be potted in August or September and sheltered to produce flowers. Many of the varieties are brilliant when in bloom.

6. *Carnation,* beautiful and fragrant, but too tender for the open ground in winter. It flowers in summer, and should be taken in before severe frosts occur. Propagated by pipings, layers or division of the roots.

7. *Crown imperial,* a splendid bulbous rooted plant, flowering early. Plant in autumn, four inches deep. Multiplies by offsets, and is produced from seeds.

8. *Crocus,* a small bulbous rooted perennial, multiplied by offsets—hardy, flowers very early, and is of various colours. Plant in autumn two inches deep.

9. *Columbine,* very common, very neat—many species,—perennial. Seeds.

10. *Crimson monardia,* (high balm,)—well known. Offsets.

11. *Convolvulus,* an annual, many species, as the morning glory, bell of day, &c. admired. Sow the seeds early.

12. *Coreopsis* tinctoria, a pretty annual, with yellow flowers, and a dark centre, which, when once introduced, propagates itself, as the plants which spring up from the seed self-sown, endure the winter's cold, and flower the earlier. It may be sown in September. There are several other species of the coreopsis.

13. *Candytuft,* white and purple flowering, are pretty dwarf growing annuals, the seeds of which should be sown early.

14. *Coxcomb,* an annual; like the amaranthus and eternal flower, it retains its beauty through the winter, if gathered before frost. Sow early, and in hot bed if convenient.

15. *Clematis,* (Virgin's bower.) Several species, beautiful perennial climbers—some woody—some indigenous. Seeds.

16. *Dahlia,* too well known and admired to need a description. It is one of the greatest ornaments of the garden, and often flowers from June to October. It possesses about the same hardiness as the potato, and like the potato may be started in the spring in earth in the green-house or dwelling, though the stem should not be exposed in the open ground till the first of June. A stake should be put down by each plant, which should retain but one stem, to tie the plant to as it grows. The roots may be divided into as many parts as there are sprouts. Plant from three to five feet apart in moist rich ground. The roots should be taken up after the plants have done flowering, and being suffered to dry a few hours in the sun, may be packed for the winter in dry sand, and placed in a dry cellar, or cellar kitchen. They do not bear frost or great humidity. A dozen will afford a pretty variety of colours.

17. *Daisy,* a modest but beautiful dwarf perennial, suitable for the border, producing double white and pink flowers, multiplied by seeds or offsets.

18. *Double perennial Sunflower,* produces an abundance of double showy yellow flowers.

19. *Eternal flower,* red, white, purple and blue, all beautiful, the flowers retain their colours through the winter, and, like the amaranthus and coxcomb, make a fine appearance in vases.

20. *Eupatorium,* a perennial with blue flowers much admired. Divide the roots.

21. *Evening primrose,* (onothera) several species, perennial and annual, the dwarf annual particularly handsome.

22. *Eltscholtzia,* (Californica,) a dwarf of beautiful foliage and a yellow flower, sows itself, and is long in bloom. If a little protected, the plants will stand the winter, and flower early.

23. *Foxglove,* white and purple flowering. Produced from seed. Perennial. Sow early, and cover the seed lightly.

24. *Fraxinella,* perennial, white and pink flowering, the blossoms and capsules possessing a peculiar aromatic fragrance. Seeds.

25. *Hyacinth,* a bulbous rooted perennial, producing beautiful and fragrant flowers of various colours, single and double. Usually multiplied by offsets.

26. *Hollyhock,* or holy-oak, termed a perennial, but is rather a biennial, unless the stems are prevented from seeding. It is a showy plant, of a multiplicity of colours, and some of the double varieties have all the delicacy and beauty of the rose.

27. *Iris,* or fleur-de-lis—many species, embracing different combinations of colours—is generally grown on the border, and the dwarf kinds are used for edgings. Multiplies rapidly.

28. *Larkspur.* There are several perennial species, much admired for their beauty, particularly the Chinese double flowering, which last can be only multiplied by dividing the roots—the others producing seeds. There are other species that are biennial and annual. The rocket, (ajacis,) sown in a bed in September, produces the next season, the most brilliant spikes of diversified flowers.

29. *Lily.* There are many beautiful species belonging to this genus, and several of them are natives of our woods and meadows. We have transplanted the common meadow lily, (*superbum,*) when in full bloom, and some of them, under culture, have produced from 30 to 47 flowers upon a single stem. The tyger lily is very showy. Propagated by seeds or by dividing the roots.

30. *Lupins,* several species, perennial, having showy flowers, propagated by seeds.

31. *Lobelia,* the scarlet and the blue, are both natives and are perennial, and pretty flowering plants. Seeds.

32. *Lichness,* the double scarlet, fulgens and double ragged robin (*flos cuculi*) are beautiful species of this family. These kinds propagated by dividing the roots.

33. *Lichnidia,* or phlox, several species, of various colours, coming into flower in succession. Propagated by dividing the roots.

34. *Monkshood,* the common, a blue flower, and a new kind has variegated flowers.

35. *Mignionet*—admired more for its fragrance than the beauty of its flowers. Annual—seeds.

36. *Musk plant,* a dwarf annual, with small yellow flowers, highly scented with musk. Sows itself when once introduced.

37. *Narcissus,* a bulbous rooted plant, managed like the hyacinth—blooms early, is beautiful and fragrant. The polianthus narcissus and jonquils, both elegant flowering plants, are propagated and cultivated, in all respects, in the same manner.

38. *Nasturtium,* is an annual, two varieties, with showy flowers, cultivated principally for their fleshy pods, which are gathered before they are ripe, and pickled. They are used as a substitute for caper sauce.

39. *Pæony.* The double scarlet is common, the double blush less so; but the Chinese, of which there are at least three herbaceous kinds (*Whitleji, Humei and Fragrans*) are equal in beauty, and surpass the others in fragrance. There are several other kinds of less note.

40. *Peas*—The everlasting is perennial, and there are several annuals, differing in flowers and fragrance.

41. *Pink*—a large family of plants, embracing the Sweet William, clove, China, and many other species. Some are equal in beauty to the carnation, and the pheasant-eyed, which is propagated by layers, affords at all seasons, a beautiful tuft of green foliage.

42. *Poppy,* perennial, has a very large, showy scarlet flower. There are two or three oriental species. Seeds.

43. *Poppy,* annual—many varieties, and of brilliant and diversified colours. To perpetuate double ones, those with single flowers, growing near, should be destroyed as soon as the flower buds burst.

44. *Petunia,* an annual of recent introduction, purple and white flowering—flowers very abundant, resembling in size and shape the morning glory.

45. *Purple hyacinth bean,* makes a very pretty show when trained over an arbor, or upon a wall.

46. *Polyanthus*—many varieties—a bulbous rooted plant, treated like the hyacinth. Offsets.

47. *Spiderwort,* three kinds, blue, pink and white flowered—perennials. Divide the roots.

48. *Tulip.* A great many varieties of this beautiful plant are annually imported, and the finer kinds command a high price. It may be raised from seed; but the more ready way is to plant the bulbs, which multiply by offsets. The tulip should be planted at six inches distance, in a rich soil, and the bulb should be surrounded by sand when planted. Plant three inches deep. The roots should be taken up at least every second year and divided.

49. *Violet*—many species and varieties. This has now become an amateur flower in Britain; violet shows are frequent, and prizes are awarded for the best flowers. The choice kinds have been partially cultivated by amateur florists among us.

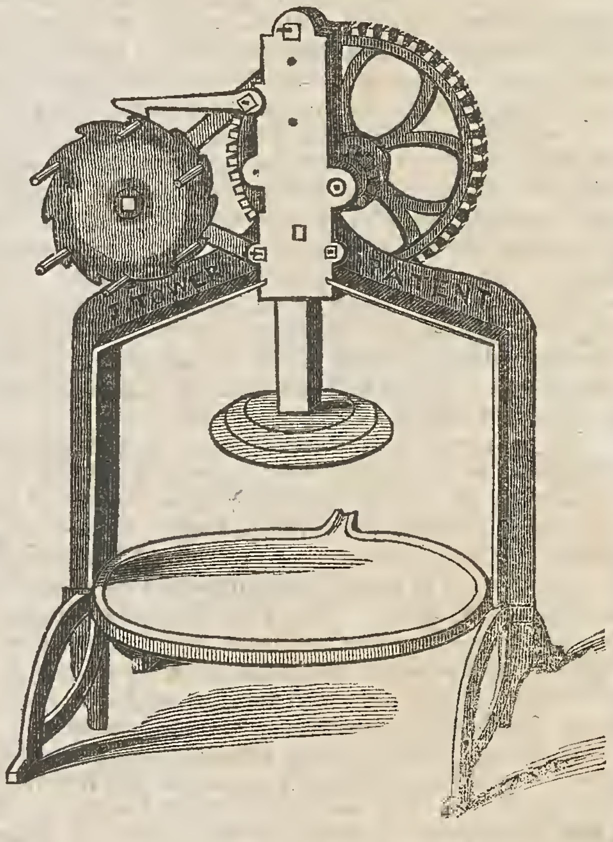
This list of ornamental plants might be greatly extended; but we opine it will be considered already too extensive for a farmer's care. If so, it admits of being curtailed to suit the taste or the convenience of the cultivator. Our woods and meadows, and swamps abound with ornamental plants highly prized in Europe; and which would also be admired here, were they not common. A collection of such as are not here enumerated may be made without much trouble or expense, which would add greatly to the beauty and variety of the ornamental grounds.

The ornamental department may be blended with the fruit and kitchen departments; it may be spread through these and the court-yard, or grounds about the dwellings, or it may constitute a distinct department, under the name of flower garden or shrubbery, combined or separate. In whatever manner it is arranged, it should be contiguous to the dwelling, of easy approach, and where it may be seen from the doors and windows.

Tower's Cheese Press.

We called the public attention to this press, of which we here give a cut, in October, 1837. The inventor, Jonas Tower, lives in Madison, Ohio.—We here figure and again notice it, because we deem it the best that has ever come under our notice; and were it in market here, we doubt not it would sell well.

[Fig. No. 2.]



The press is entirely of cast iron, except the lever. It occupies about two feet square, and stands about three feet high. It is on the principle of continuous pressure; the power may be increased at pleasure, to almost any required extent, by a youth of twelve years old. It is simple, and can hardly get out of repair. Its advantages are—

It occupies but little space; and

The pressure may be graduated at pleasure.

The Silk Business.

An uncommon degree of public attention has been turned to this subject during the last few months. A national convention of silk growers was held at Baltimore, in December, as we have already noticed. Since which time, state conventions have been held in Maryland, Pennsylvania and some other states, and the "*Journal of the American Silk Society, and Rural Economist,*" has been commenced at Baltimore, by J. S. SKINNER, the original publisher of the American Farmer, assisted, we believe, by G. B. SMITH, two gentlemen eminently qualified to conduct a publication of this kind. The Journal is to be published in monthly numbers, each number to contain thirty-two pages, 8 vo., at two dollars a year, to be paid in advance. A prospectus of the Journal may be seen at the office of the Cultivator, where subscriptions for the work will be received. The first number contains the proceedings, including the debates, of the national convention, and of the American silk society, an address to the people of the United

States, which we insert in another column; and several other matters of great interest to the silk grower. We commend this publication to the notice of all who have commenced, or who intend to commence, the silk culture.

Extensive preparations are making, and heavy capitals have been put in requisition, to extend greatly this business the coming season, particularly in the middle states, where we think it can be managed with the greatest economy; while the northern and eastern states will probably be found to excel in growing the sugar beet, as this is more properly the beet zone—the root grown here abounding more in sacharine matter than that grown at the south. This is inferred from the fact, that the beet grown in the northern departments of France furnishes a richer juice than that grown in the southern departments.

The Ohio State Agricultural Society,

Was organized early in January. Samuel Spangler was appointed president, and William H. Harrison and eighteen others, vice-presidents. It has commenced its operations with a spirit which presages much good to the state; and which will tend to arrest, we doubt not, that exhausting system of culture, common to the settlers on new lands, which has so lamentably impoverished the soil in the old settled states. The society resolved to establish a state agricultural journal—to petition the legislature for pecuniary aid, and to provide for an agricultural survey of the state;—to inquire into the propriety of invoking the aid of the national and state governments in purchasing, for the use of the society, a farm, or a tract of land, for the purpose of making experiments, and establishing thereon an agricultural school; and to take measures for the organization of county agricultural societies, of which, however, several already exist.

The establishment of a state agricultural journal, will no doubt accelerate agricultural improvement; but its potency and its benefits will be more than doubled if the society can introduce it into common schools, or common school libraries. It will contain much matter of interest to the boys, and will beget in them a taste for useful inquiry and experiment; and in this way too will incidentally be brought under the eye, and made to exert a benign influence on the practice of thousands of parents, who, if they read at all, must in this or some other way be decoyed into the habit. [We beg to make our acknowledgments to the society for the compliment it has done us, of enrolling the name of the Conductor among its honorary members.]

To Preserve Poultry in Winter.

About the 15th November, the Conductor purchased a quantity of poultry for winter use. The insides were carefully drawn, their place partially filled with charcoal, and the poultry hung in an airy loft. It was used through the winter, till about the first of February, and although some was kept seventy days, none of it was the least affected with must or taint—the charcoal having kept it sweet.

Relative Advantages of Large and Small Sheep.

In the proceedings of the Penrith Agricultural Society, England, we find some remarks of Mr. Gray, on the comparative profit, to the grazier, of large and small breeds of sheep, which we transfer into our columns for the benefit of our readers—of the buyer as well as the seller of mutton. It is a mistaken notion, too prevalent, that the largest carcases are the cheapest, or the very fat ones the most palatable and healthy. On the contrary, the Devon cattle, South Down sheep, and the Berkshire pig, which are considered medium sized breeds, give better beef, better mutton, and better pork, than the larger and coarser breeds of these animals. The former give more *fat lean* meat than the latter, that is, the fat is better intermixed with the lean; the meat is more rich, tender and economical for the table, although the proportion of clear tallow or fat may be less. But our extract refers merely to the profits of the grazier. It seems that in their awards at the fair, the judges had somewhat favored the small breeds of sheep. On the health of the judges being given, Mr. Gray, the chairman, addressed the meeting, and among other remarks, made the following:

"I dare say that the opinion of the judges, with respect to sheep, has been much censured, although I declare I have not heard any observations to that effect. My reason for supposing so, is this, that people who have not great experience of the qualities and niceties connected with every description of stock, are apt to look principally at that which fills the eye, and to form a favorable opinion of animals upon a large scale, and this is particularly the case with respect to the Leicester sheep. I have had considerable experience with sheep of this description, having, in former times, kept a flock of between nine hundred and one thousand Leicester ewes, and therefore I have some title to speak upon the subject. I say, then, that the largest sheep are the least profitable. If it can be ascertained, as I believe it has been, that you can feed on an acre of land a greater number of pounds of mutton in carcases of from 18 to 20 lbs. per quarter, than in carcasses of from twenty-eight to thirty lbs., then every one must agree that the advantages are on the side of the smaller carcases. The reason of this is obvious; in times of drought and scarcity, a small animal can collect for itself as much food as a larger one, and having a smaller carcass, it derives more advantage from it. Whilst, therefore, the larger animal is losing in condition, the smaller one, if not improving, remains stationary; and when the period arrives at which abundance of food can be obtained, it almost immediately re-assumes its position, and is fit to go to the market sooner than the larger animal. I do not presume to offer any thing like dictation to this meeting, but I am confident that those gentlemen present, who have had experience on this subject, will bear me out in saying, that there are advantages in breeding the description of stock to which I have been referring, which do not attach to animals of better appearance and larger size."

Economy in keeping Horses.

Roberts, in his Agricultural Economy, maintains that one pair of horses, well kept, are sufficient team to work a fifty acre farm, and to work it well, under the alternating system. It has been proved, he says, that a team going at the respective rates of a mile and a half and two miles an hour, will plough in nine hours as follows:

Width of furrow.	Rates per hour.	A.	R.	P.
Eight inches, ..	One mile and a half,	1	0	0
Nine inches,...	ditto,	1	0	20
Eight inches, ..	Two miles,........	1	1	10
Nine inches,...	ditto, ...	1	2	0

Three things requires attention from every man who wishes to keep horses well and economically:

1. The food must be natural for them;
2. The quantity of food requisite to keep their condition equal to their work;
3. The best manner of giving them their food, with the view of its being speedily eaten, so that they may lie down to rest.

The natural food for the horse, says our author, is corn, hay and grass; but that under artificial management, there may be advantageously substituted for natural food, or conjoined with it, potatoes, parsnips, carrots, turnips and mangold wurzel, together with straw, bean (and corn) stalks, pea haulm, vetches, clover and other cultivated grasses, cut green.

Hay is sufficient to keep a horse to look at; but corn is indispensable to enable him to stand hard work. A horse requires thirty pounds of dry food a day, of which a part must be corn or its equivalent; to those which work, one pound of good oats is equal in nutriment to three pounds of good hay. Heavy oats are worth more, pound for pound, than light oats, as will be seen by the following scale:

Weight per bushel.	Produce in meal.	Produce in bran.
42 lbs.	25 lbs. 2 oz.	16 lbs. 14 oz.
40 lbs.	23 lbs. 6 oz.	16 lbs. 10 oz.
38 lbs.	21 lbs. 12 oz.	16 lbs. 4 oz.
36 lbs.	20 lbs. 3 oz.	15 lbs. 13 oz.
34 lbs.	18 lbs. 11 oz.	15 lbs. 5 oz.
32 lbs.	17 lbs. 5 oz.	14 lbs. 11 oz.
30 lbs.	16 lbs. 1 oz.	13 lbs. 15 oz.

In general, the different kinds of grain are nutricious in proportion to the weight; while two pounds of green food or roots, are considered equal to one of dry.

"Whatever fodder be used," says Mr. Roberts, "it should be supplied in such a form as to be eat forthwith, that the poor animals should enjoy refreshing rest: to secure this, *the fodder should be cut or crushed*, and placed in a MANGER"—not a rack. "When the respective feeds will have been consumed, every horse will lie down to rest; his hunger being satisfied, there will be no temptation to keeping him standing for hours, as would be the case, were his rack stuffed with hay, according to the too general custom of farmers. The nutriment contained in every kind of grain depends upon its weight." It is to be remarked, that concentrated food, as grain, will not do alone, there must be something to increase the bulk, to impart the stimulus of distension, before the functions of digestion can be carried on in perfection. Horses, therefore, and even fattening animals, which are fed high with grain, require cut hay, or even straw, for this purpose, independent of the nutriment they afford.

"When the quantity of hay supplied as food for horses," says Mr. R. "has been increased, and the quantity of oats diminished, it has been found that the animals, though they appear to improve, as to the fatness of their looks, were nevertheless not so able to stand hard work; and on the contrary, when the corn has been increased, and the hay diminished, it has been found that though the animals might, as to appearance, be leaner, yet that they were stronger, more equal to hard labor, and in better working condition."

The following different component parts of a ration of food for a horse, have been publishod in the Sporting Magazine, and are worthy of notice, as coming from a proficient in the management of horses.

	lbs.	lbs.	lbs.	lbs.
Corn, peas or beans, ground or crushed,	5	5	10	5
Hay, cut into chaff,................	7	8	10	8
Straw, do	7	10	10	0
Potatoes steamed,.................	5	5	0	0
Malt dust or oil-cake,..............	0	2	0	2
Bran,..........................	0	0	0	7
Grains, ...	6	0	0	0
	30	30	30	30

Other articles, such as apples, carrots, parsnips, turnips, beets, &c. may be substituted. If the food is found to be heating, small doses of nitre or flour of sulphur may be found beneficial; and about two ounces of salt should be given twice or thrice a week.

Foot Rot in Sheep.

We find in our last Farmers' Magazine, the following directions for curing this disease, which are simple, cheap, and we should think effectual.

"Towards evening draw the lame sheep from the flock, have the hoof of the deseased foot, as far as it has any dirt or fester under it; wipe it dry and clean, and bathe the tender parts in the evening with a feather previously dipped in butter (muriate) of antimony; keep their feet dry during the night, and on the following day they may be turned into a pasture by themselves, where they will daily become better. At the expiration of about a week they should again be examined. The majority of them will be found perfectly well, and may be allowed to join the sound flock, as they will be clear of all infection. Perhaps about one in ten will require a little more pairing with a knife, and a very slight redressing of the sore place, with the feather prepared as before. JOHN BERKETT.

"*Dallston, Oct.* 1838."

Journals of Education.

We have recently received three new publications of this class; one from Boston, one from Hartford, and one from Detroit. They all evince talent and good judgment in their conductors, and an awakened and praiseworthy zeal in the community. We consider the increased circulation of periodicals on education and agriculture, as among the greatest improvements of the day, and as the certain precursors of an improved state of society.

Insect Enemies.

Three prescriptions against the depredations of insect enemies, which prey upon our garden and field crops, have been mentioned to us, of the efficacy of which we make no pretensions of a personal knowledge; but which being simple, and within the means of every family, and the trial of which will cost little or nothing, we give as we received them.

A good lady, now a widow, whose husband was, we believe, a gardener, says, that the sowing of buckwheat, broadcast, in the preparation of a turnip crop, is efficacious in preventing the ravages of the turnip fly, and that when the turnips have got their rough leaves, the buckwheat may be cut up without danger; that her husband always had good turnips with this precaution, and seldom saved his crop without it. Another widow lady gives us a like assurance, from her own practice.

A highly respectable gentleman assures us, that he is never troubled with the yellow bug upon his cucumbers and melons—because he always scatters upon the hills, at planting, a little lettuce seed.

And our Michigan correspondent, Mr. Beden, maintains stoutly, that poppies are a sure protection against every species of obnoxious bug and fly.

There is no doubt that the odor of many plants is obnoxious to certain insects, and will protect from their depredations. Thus Russian leather is safe against the moth that often destroys the binding of books, on account of the odor of the bark with which it is tanned. Spirits of turpentine, and the shavings of cedar, will protect clothing from the same and other insects, on account of the odor which they impart. The elder and hemp are obnoxious to many families of insects; and we do not see why buckwheat may not be so to the turnip fly, lettuce to the yellow bug, and poppies to many flies, bugs and other insects. It will not cost much to try either or all of them; and if successful, the the secret is worth knowing.

Templemoyle Agricultural School.

We gave in our July number an account of this school, recently established in Ireland, by private subscription. We have just seen an account of the first examination of its pupils. It is an establishment designed to afford a practical instruction in agriculture and the simple sciences, with wholesome food and a comfortable home, to one hundred pupils, at £10 ($44) per annum for each. "The importance of the system brought into operation at Templemoyle," says the writer whom we quote, "strikes us as being so vast, that questions of a party nature, however exciting for the time they be, sink into utter insignificance when compared with a principle so solid, and so essential to the well being of the country, as one which comprises the agricultural and liberal education of the farming classes." The exhibition was attended by a great concourse of the most highly respectable people; and the examination was conducted by competent gentlemen in the different departments of istruction. The boys that had been more than six months at the school were examined by James Anderson, Esq. in the presence of some of the first agriculturists of the country. The questions embraced the whole theory and practice of agriculture,—the use of the instruments of husbandry, the best methods of draining land, the laying out of ridges and water furrows, the management of horses and cattle, the different modes of cultivating the several crops, with the most approved rotation of each, &c. &c. The answers gave high satisfaction. Capt. Portland examined a class in botany, "and we question much," says the report, "if among the sons and daughters of the wealthy and learned, would such intimate knowledge of an abstruse and technical science be exhibited."

When shall we enjoy the pleasure of witnessing the examination of an agricultural school in New-York? There are thousands of parents who would like to avail themselves of the advantages of such a school for their sons, but there are few, very few, seemingly, who are willing to come forward to assist to establish one, for the benefit of their sons or their country. We might possess all the advantages of such a school in a few months, if ten gentlemen of influence would embark spiritedly in the enterprize. We have a law of incorporation; we have a quarter of the requisite sum subscribed, to put a school in operation, on a liberal and enlightened scale—but as it can furnish no political capital, and cannot be made a matter of speculation, it lacks the popular incentives to favor and patronage.

The Smithsonian Bequest.

A Mr. Smithson, who it is said, was a natural son of the Duke of Northumberland, a gentleman of liberal education, a traveller and a bachelor, who died some time since at Genoa, left his entire estate—*for the diffusion of useful knoweldge among mankind*, and left it to the wisdom of Congress to apply the avails. Mr. Rush has brought from England, $508,318.46, which has been paid into the national treasury, and most of it vested in productive stocks. The question is now before a committee of Congress, how this money shall be expended. Among other plans of appropriating it beneficially, one has been submitted for applying a part of it to the establisment of a national school of agriculture, near the seat of government, a plan and estimate of which has been submitted to the committee, by C. L. Fleischmann, a graduate of the royal agricultural school of Bavaria. The project is a noble one, and we hope it will be adopted. And yet we fear the the contemplated location is a bad one. We doubt if practical agriculture can be taught well, where agricultural labor is considered rather a servile employment. We think the south would prefer to send her sons farther north for an agricultural education; and that the north would not like, for a like purpose, to send hers so far south.

Wool Statistics of Vermont.

Vermont is peculiarly adapted to grass husbandry, and to the culture of the grains and roots for feeding and fattening farm stock. Being mostly of primitive formation, there is not lime enough in the soil to render the wheat culture profitable. Indian corn is liable to be injured by the early and late frosts. The oat, the potato, the ruta baga, and we doubt not the beet, do well; but the herbage, and pasture, are peculiarly rich and abundant. Her hills, and even her mountains, afford an appropriate range to cattle and sheep; and these, it seems, and particularly the latter, have for some time, attracted the attention, and very properly too, of her farming community.

It appears from the statement of Henry Stevens, made at the Caledonia cattle fair, in September last, that the whole number of sheep in the state in 1837, amounted to 1,166,234; that if averaging the fleeces at 2½ lbs. each, the aggregate would be 2,915,385 lbs. of wool; that there being 300,000 inhabitants in the state, and estimating that each requires, for all purposes, nine pounds annually, the surplus produced in the state, over and above the wants of her population, is 215,585 lbs. But Mr. S. goes on to state, that Vermont having no manufactures at home, sells her wool to the manufacturers of other states, and purchases her woollen goods in return, either of domestic or foreign fabrication, and pays for them, in the charges of collecting and sending her wool abroad, in converting it into manufactured goods, and in bringing them back into the state, sixty cents per pound over the prime cost of the wool, or in the aggregate, $1,600,000. Mr. Stevens argues from these premises, that Vermont ought to establish her own manufactories, for which she has capital, abundant water privileges, and all the materials for constructing them. There is no doubt but the suggestion is a wise one, though the benefit would not be to the extent stated. Were the wool manufactured in the state, the fabrics would be principally sold in Boston and New-York, and brought back by the retail vender. The manufacturer could not wait the tardy returns from the local market; the merchant would contrive to make his purchases at the great depots, and even the consumers, such is the force of habit, would buy them the more readily by their being denominated *boughten* goods.

New Agricultural Journals.

The *Boston Cultivator*, has been commenced at Boston, by Mr. Buckingham, one quarter part of which is to be devoted to agriculture.

The *Farmer's Monthly Visitor* has beem commenced at Concord, N. H., by Isaac Hill, formerly editor of the New Hampshire Patriot, and subsequently senator in congress and governor of the state.

In our young days, while conducting a political journal,—and by the bye, political journals were then less abusive, if not more tolerant, we think, than they are now—we received in exchange, the Albany Register, published by S. Southwick, the Balance, published by H. Croswell, and the New-Hampshire Patriot, published by I. Hill, all then distinguished political journals. These gentleman are all now engaged in other, and we believe better employments—in improveing the moral, social and agricultural condition of their country; and may success and happiness crown their labors; and may others, seeing their good works, profit by their example.

We hail the increased circulation of agricultural journals as highly auspicious to the best interests of our country. Were their circulation increased fifty fold, the country would be proportionally benefitted. Our system of husbandry in the main has been wretchedly bad. It has greatly deteriorated the old settled portions of our continent, and is rapidly exhausting the virgin fertility of the west. These agricultural periodicals are calculated to arrest our downhill course—to expose the errors of our practice, to introduce improvement, and to elevate the character and standing of this great business of our nation. They *will* produce a benign effect wherever they circulate, and it is the interest of all to endeavor to extend the sphere of their usefulness.

Editorial Pilfering by Wholesale.

We have just received the entire first volume of the "*Ohio Cultivator*," published at Belmont, Ohio, by Thos. S. Reid, comprising 160 pages 4to. On running over the pages, we find that the editor has filled thirty-two of them entirely, and to the amount of five or six more in parcels, making nearly one quarter of the entire volume, with matter which was first published in our paper—either written by the Conductor or his correspondents—and which justice, as well as the universal practice of editors, entitle us to credit for—*without intimaitng that it originated in our paper!* If the editor is an old man, he ought to *know* better, and *do* better. If he is a young man we hope he will *learn*, that "honesty is the best policy," the world over. We know of but one excuse—and that is, that the *Ohio* Cultivator may claim to be a legitimate child of *the* Cultivator at Albany—and justify itself upon the principle, that what belongs to the father belongs to the son. Be the fact what it may, we forgive the past, and hope, for the credit of the name, that we shall not have cause to repeat our admonition.

Agricultural Items.

A Steam Plough, of a very peculiar construction, has been invented in France, with which it is said four miles of ground can be excavated, with an engine of only eight horse power, to the depth of a foot, and the breadth of two feet, in a single hour. The earth as it is turned up is thrown into a sort of sail, which throws it to a distance of sixty feet. Its particular advantage is in the excavation of canals.—*Farmers' Magazine.*

Beet Sugar Manufactories.—Bavaria, with a population of a little more than three millions, has eighty-nine beet sugar manufactories in full operation, and many more ready to commence.

Bone Manure.—In a circuit of ten or fifteen miles round Driffield, in Yorkshire, says the Farmers' Magazine, three to four thousand tons of bones are brought yearly from Hull, as manure, and this independent of a considerable quantity obtained from the mills at Beverly and Malton. Bones are imported into England from Russia, Sweden and South America. A bone mill has been erected at Waterford, Saratoga county.

The Turnip Fly, although one of the smallest, is yet one of the most destructive foes to British husbandry. The British societies have offered many premiums, and awarded several, for preventives to its ravages, but all to little purpose. At length a patent has been taken out for a machine which it is confidently affirmed will destroy not only the turnip fly, but other insects and their eggs deposited on the surface—*by means of steam!* A boiler, to generate steam, is mounted on a small pair of wheels to be drawn between the rows. The steam passes through a pipe behind the boiler, into flat conductors which extend along the vacant space between the rows of turnips, and nearly touch the surface of the soil, so that a perpetual strong jet of steam is discharged against the surface of the ground, which it is said effectually destroys the fly in a chrysalis state, as well as the flies themselves, who it is generally believed, throw themselves down off the turnips as soon as they are disturbed by any movement of the plant.

Short Horned Cattle, seem to retain their former large prices in England. Extensive sales of large herds are recorded in the Farmers' Magazine. The average prices of cows, heifers and bull calves are from forty to fifty guineas, and some choice cows and bulls have sold as high as 100, 200 and 230 guineas each. The guinea is a little less than five dollars.

Spade Husbandry.—A notable illustration of the advantages of spade husbandry was shown to the Derbyshire Agricultural Society in October, by C. Pole, Esq. Wheat grown on land dug, and an adjoining piece of like quality which had been worked by the plough. The ears on the dug piece were longer, by at least an inch, than on the ploughed, and the product greatly superior. Mr. Pole estimated the product on six acres of dug ground to be worth £207, while that on the ploughed—32 bushels per acre—would be but £120, leaving a balance in favor of the former, after deducting £18 for digging, of £69—$306.36, or 51 dollars an acre.

Notices of Correspondence.

Rockwell's Corn Planter.—See advertisement in last number. This machine plants two rows at a time, at any required distance, and any required number of kernels in a hill. It makes the furrows, drops the seed, covers it and rolls the ground at one operation, propelled by a horse and guided by a man. It was exhibited at the fair of the American Institute; since which the price has been reduced from fifty to thirty dollars. It is said to be simple in its construction; easily taken apart and again united, and is packed for transportation in a box of fivefeet by twelve and a half inches, and eighteen inches deep. Address D. S. & F. A. Rockwell, Ridgefield, Ct.

Oil-Cake—"*A new subscriber*," inquires as to the value of oil-cake, the mode of using it, &c. We have had but little experience in the matter; yet we know it is extensively used in Britain in fattening cattle and sheep —large quantities being annually imported from Holland and other parts of the continent for this purpose; and that it is also used in the United States for the like purpose. It cost us, some years ago, ten dollars a ton. We do not know the present price. It is a valuable auxiliary in fattening cattle and sheep, and was worth all we paid for it; though the flesh it adds to the animal is rather gross, or of inferior quality. It is given to animals in three ways—ground to powder, broken into small pieces, or reduced by water to a jelly. The first mode is the most common, though we think the last most serviceable. It is fed with roots, hay, &c. in about the same quantities as corn meal.

Improvement by selecting Seed.—George P. Frost, of Ithica, Tompkins, has sent us two samples of very large corn, *Tuscarora* and *Sweet Corn*, which he says he has greatly improved in size, by carefully selecting the seed for some years. "I have succeeded in enlarging the grains of the Tuscarora," he writes, "to nearly double the ordinary size, and I think the sweet corn is three times as large as the grains used to be, and both still retain all their former sweetness and richness for table use." Mr. Frost's closing request shall be complied with, and he may compensate us by sending us a larger sample of his improved corn in the spring.

The Brussa Mulberry.—Mr. Abraham Marsh, of Tolland, Ct. has propounded to us several queries in relation to this species, or variety of the mulberry. Until experience shall enable us to speak with more certainty upon this subject, we must refer Mr. M. to the remarks upon it in our January number, page 188.

More Insect Enemies.—Daniel Andrews, of Meadville, Crawford county, Pa. writes, that, "insects nearly ate up or destroyed much of the last summer's crop. One kind got in the wheat, when nearly ripe, and was threshed out in pecks. At times and places, another kind were seen travelling in thousands across the roads to buck wheat fields, which in some parts were wholly destroyed by them. Another kind attacked the cabbage, at the root and on the leaf. At the roots of some plants, there would be thousands not much larger than pin heads; and the only resort was to get a hen and chickens among them."

The Pea Bug.—The habits of this bug are too well known to need a description wherever they have appeared. But as there are many districts which have not been visited by them, it may be well to remark, that as soon as the pea begins to form, the perfect insect punctures through the pod, and deposites the egg or the young in the pea, which feeds upon the pea, grows and matures, and comes forth the next spring a winged insect. The maggot is in the green pea when it is served up at table, but the great injury to the crop occurs after it is gathered—the insect consuming a great portion of the interior. Mr. Jason Smith, of Tyre, in this state, has communicated to us his practice for the last four years, which he thinks has preserved his peas from their ravages. It is to stow away his peas, without threshing, till winter. The vitality of the insect is believed to be destroyed by this means, and of course the parent stock. A somewhat similar mode has been adopted, we understand, to smother and destroy the insect, by threshing them as soon as they are brought from the field, heading up the peas in perfectly tight barrels, and keeping them in this state till winter.

Gypsum.—"A young subscriber," who dates from Virginia, would not be edified, and we fear our readers would not be benefited, by a philosophical disquisition of the question he submits to us. Opinions as to the *modus operandi* of gypsum are various. Even those who ought to know best are not agreed in the matter. *Our* opinion has been so often expressed in the Cultivator, that our correspondent will find no difficulty in gathering it from our volumes. See pages 80 vol. I. 7, 128, vol. III. 55, vol. IV. &c.

Application of Lime.—"N." who dates at Locust Grove, is referred to pages 104, vol. I. 11, 54, 84, 100, 116, 149. vol. III. &c. for answers to his queries. We remark, however, that the first question to be considered is, whether it is desired to have it operate as *caustic* or *mild* lime; that when applied to sod ground, it should be spread *before* the sod is turned over, in preference to being spread *after*; and that it is seriously injured, as *quick*-lime by being long exposed, in heaps of "two or three hundred bushels," to the weather; and that if *mild*, or air slaked, it will probably receive little injury or benefit.

John M. Millikin's proposition.—We have received a printed sheet, containing a proposition of this gentleman, who resides in Butler county, Ohio, to raise a fund, by voluntary subscription, of $1,000, to be awarded in 1842, in three premiums of $500, $300 and $200, for the first, second and third best improved, cultivated and stocked farms in the county. Subscriptions to be received till January, 1840. We have not room for the details; but we think the plan is a good one, and that if carried out with spirit, it will soon add thousands of dollars to the value of the agricultural products of Butler county. There is nothing like competition to accelerate improvement; and the more numerous the competitors, the more substantial the benefit.

Sugar Beets.—Sherman McLean, of Royalton, Niagara county, has raised 400lbs. of sugar beet seed—the roots appear still sound, and he asks if they will produce another crop of seed if they are planted out? Our answer is—they will not.

Sugar Boilers.—We have received a subscription from Joseph P. Plummer, of Richmond, Ia. and his friends, on condition that we publish in our March number, the best construction known to us for a furnace to boil "sugar water." We give, from perhaps the best sugar boiler in the state, a description both of the furnace and boilers, in another column, under the title maple sugar, which we hope will prove satisfactory not only to our correspondent, but to many other of our readers.

Smith's Contracting and Expanding Cultivator—A drawing of which has been sent to us, possesses one property not common to any other implement of this name we have ever seen: It may be contracted or expanded at pleasure, while the team is in motion, by the man who guides it, merely by moving one of the handles to the right or left, which is connected by a half inch rod with a cast iron cog wheel, four inches in diameter, which works in two slides screwed to the slats.

Nitre in Steeps.—In reply to the inquiry of James Boyle, as to the quantity of salt petre we use in steeps for seed corn, &c. our practice has been to use half a pint of crude India salt petre to a half bushel of seed. Less would suffice, and more would not prove injurious. We dissolve the nitre in water, and then apply it to the grain.

Society for the Diffusion of Useful Knowledge. We have received sixteen pages of manuscript, *in part* of an answer to the communication of our New-Hampshire correspondent, in relation to common school libraries. They came to hand too late for this number, but will be inserted in our next.

☞We thank our Correspondents,

For the valuable communications with which they have enabled us to enrich the columns of this number of our paper, and to render it as valuable, in original matter, probably, as any number we have published. Our communications exceed thirty in number; and, zealous as we feel in agricultural improvement, it seems to us, that some one of them may be made to benefit every subscriber to the amount of his annual subscription. The very excellent communication of Mr. Seeley cannot fail greatly to benefit every farmer who has a peat swamp, and is desirous to profit by it. The letter of Mr. Garnett, besides abounding in other useful matter, will furnish useful hints to our northern as well as southern patrons, who would mind their habits and their practice. The articles upon corn crops, the culture of the carrot and ruta baga, are replete with practical instruction. The communication of V.—and we are happy to add that our correspondent has promised a continuation of his favors—will be read with interest by all who are anxious to raise the standard of agricultural education. Indeed, we believe all the mass of matter inserted under "correspondence," will be found promotive of the great interests of agriculture and education.

And we beg leave to call the attention of *sugar-boilers* to the notice, under maple sugar, of the excellent mode of management adopted by an eminent sugar-boiler of Jefferson county; and also, of our readers generally, to the reports made in the State Agricultural Society and in the Agricultural Convention.

We are drawing out a vast deal of practical knowledge, from the richest sources in our country, calculated greatly to profit thousands, tens of thousands, nay millions, of American farmers—if they will but read, reflect and imitate.

Acknowledgments.—Three *very beautiful* apples, but not so rich in flavor as some of our old favorite varieties, from an unknown friend, the letter accompanying them having been lost; seeds of the Bayberry, Santafee wheat, and a new variety of corn, from Major Soulard, of Galena, from plants grown in the Major's garden, some of the wheat produced fourteen heads, beside the central one, upon a single stalk. We hope the opinion that this wheat will prove valuable, may be confirmed—unknown seeds from Columbus, Ohio, and from Mr. Hathaway, Rome, seeds of the "golden squash of France," described as splendid in appearance, fine in flavor, and of very large size, brought from the garden of the banker Rothschild, at Paris, in 1837. Mr. H. has grown them one year.

CORRESPONDENCE.

On Alternating Crops and the Causes of Deterioration in Virginia Lands.

December 1st, 1838.

Dear Sir—I have very often had occasion to remark, that the man who ventures to make even *one* speech in public, has generally to make two or three more, by way of explanation; and so it is by writing. But whether this be owing to the imperfection of language, or to the great carelessness of most of us in studying it, is foreign to my present purpose,—which is to explain, (if I can,) some things in my last letter, which you seem to have misunderstood. First, however, let me assure you, my good sir, in your own language, that no "spirit of controversy" actuates me; my sole object being to elicit truth in regard to a matter highly important to all our agricultural brethren.

You have gratified me much by expressing the belief, that "were our views mutually understood, there would be found to be no great matter of difference between us;" and it is the hope of making that difference still less, which induces me to address you a second time, on the subject of "*Rotation of Crops.*"

I certainly had no intention to undervalue, and still less to condemn the practice altogether. My design was merely to prove, that its advantages had been most extravagantly exaggerated by imaginative and theorizing writers, who often mistake their own fancies for facts, and thereby have done real injury to our cause, when they meant to do good. To guard against misconstruction, I declared my belief that "*the best system of husbandry is inseparably connected with, and dependant upon both the rotation of crops and manuring; but chiefly the latter.*" When, therefore, I stated numerous instances of good and apparently equal crops of *the same* or *similar kinds*, having been made on the *same land*, for a long term of years, in uninterrupted succession;—some *with manure*, but others entirely *without it*; I did not anticipate the possibility of appearing, either to yourself or others, to contradict myself. I meant no more than to prove that the rotation doctrine had been extended much too far by its chief advocates, who had thus produced doubts rather than conviction of its real advantages; for surely if it can be violated in very many instances, for half a century, (as you yourself have admitted,) without any discernable injury, the truth of the assertion, that destructive injury takes place notwithstanding, is not yet quite as clearly demonstrated as the fact that "the sun shines daily," which was all I meant by my objection to your apparently universal rule. *As such*, I could not admit it; neither could I receive it as any thing more than a conjecture, not sufficiently sustained by actual experiments.

One of my exceptions to the universality of the rotation doctrine, (for I have never questioned its general utility,) was, the constant succession, for many years, of corn and oats in two of the largest counties of Virginia, *without apparent injury to the land*. To this you answer, "*are corn and oats the same crop?*" as if I had actually called them so; whereas, I called them only "*white crops*;" the constant succession of which, on the same land, is forbid by the rotation doctrine. "Besides," (say you) "the pea, the bean, or the vetch, which always" (not always, but generally,) "accompanies the oat, and which is turned in as food for the corn—*is this nothing?*" My letter gave the answer in anticipation, for it states that the inhabitants of those counties ascribed the preservation of their lands to the turning under of this natural growth. This you seem to admit, for you ask "is not this virtually a *three* coursed system?" I have not denied it. But if so simple a process, forced upon men by their Maker, can prevent the fertility of an extensive territory from wearing out, may not some small indulgence be extended towards the scepticism of those who regard the complicated rotation of crops generally prescribed in our books, as a sort of "king-over-all," for exhausted lands, pretty much in the same light that they do the innumerable recipes in our old books on farriery, which rarely consisted of less than ten or a dozen ingredients, to cure a horse, even of the belly-ache, when not more than one or two of them perhaps, were worth a straw. Some medicine I believe to be quite as necessary for *sick land*, as for *sick horses*; but for both I am persuaded, the more simple the restoratives are, the better; and in the case of land that manured *without any rotation whatever*, is incalculably better, (if they must be separated,) than any rotation ever yet devised by man, can possibly be, *without manure*; although I again repeat that I deem it best to use both.

Among the proofs I adduced in support of my objection to your doctrine, as I, at first, understood it—*that* upon which I most relied, was, the apparently equal crops of *corn* after *corn*, for a long term of years, *without* any intervening crop whatever, and *without* manure of any kind. To rebut these facts, you offer only the general conjecture, that a soil *may* contain so much of the specific food, either of wheat, corn, tobacco, &c. as to last apparently, without diminution, for "*forty or fifty years.*" I asked no more to verify the inferences drawn from the facts which I stated; and this assurance I hope will, in a great degree, excuse my dissent from a rule, which you appeared to lay down as *universal*, but which I am now satisfied you intended to be understood as only *general*. In this sense, I am perfectly willing to understand and to treat it; notwithstanding you appear to have treated my exceptions to it, made under a misunderstanding of your intention, as proofs of my unqualified enmity to rotation crops of any kind. If *I* could misunderstand *you*, it is nothing remarkable that *you* should misunderstand *me*. Far, therefore, *very far*, am I from imputing to you any design to pervert my meaning; for I have full reliance on your justice, as well as on the sincerity of your wishes, to render every communication to your paper available to the advancement of our cause, so far as you can make it so, in accordance with the principles and notions which first prompted you to undertake that truly valuable work. In thus expressing my cordial approbation, both of your purpose and of the means to which you resort for its accomplishment, I say no more than my feelings and judgment both prompt me to utter. But being personally a stranger to you, this declaration might possibly lead you to suspect, without my earnest assurance to the contrary, that I was attempting "to feed you with soft corn," in order to deprecate or to dilute criticism, should you think I deserve it. True it is, that I have not quite so strong a fancy to provoke it as the valorous Don Quixotte had for attacking giants, and making an exterminating war against wind mills; but had I feared any severity of remark from your pen, I should have taken the wiser course to keep my scepticism to myself; well knowing that every editor of a public journal, who chooses to avail himself unfairly (as so many do,) of his position, may, in every controversy with others, award the victory to himself. But having no suspicion that you belong to that dextrous class who are always for playing the game of "cross *I win*, pile *you lose*," I shall proceed a few steps further in attempting to explain my former letter, with the hope of reasoning myself, if possible, from the suspicion of utter infidelity relative to the rotation doctrine.

The cases which I stated, of *the same* garden vegetables, and of cotton appearing to produce equal annual crops, on *the same land*, for a long term of years, without any discernible deterioration, either of the soil or the crops, were cited to prove that this had been effected without any alternate crop whatever, unless manure could be called a *crop*; and consequently demonstrated, in these cases at least, that the fertility of the lands and the equality of the crops had been maintained *without rotation*.

The cases of corn and oats—both "white crops," although not "*the same*," in constant succession, for a still longer period, and without the intervention of any thing but the natural growth of the wild pea or bean, turned under before the corn was planted, were given also to prove, that at least half a century of such a course had been insufficient to produce any apparent diminution in the crops; and the inference I drew from *these* cases was, not that rotation was altogether worthless, but of less advantage than was generally claimed for it; since here again, it had been found unnecessary, for at least fifty years, throughout a very extensive territory, where the soil did not seem materially different from that of thousands of acres, in other parts of our State. It is true, that I did not call this "virtually a *three* course system;" but I expressly stated, that the inhabitants themselves ascribed the preservation of their lands to the ploughing under the wild bean or pea, between the crops of corn and oats. Admit they are right, and what does it prove? Why, that this very simple alternation answers quite as well as any of those very complicated and troublesome systems of rotation, *with* which our agricultural books abound, and *by* which I have never yet seen any land improved, unless some one or more of the crops which constituted the course were returned to the land, instead of all being taken from it; and unless also, manure was plentifully used during each rotation. Apply this, in proper quantities, to any two crops whatever, either the same or different; *this* which is to plants what the life blood is to the human body; or make use of lime, gypsum, marl, or ashes, and my belief is, that we need not trouble ourselves much about any system of rotation whatever; although I repeat what I have said before, that some I deem better than none.

The cases of equal corn and tobacco crops, each annually made on *the same ground*, respectively appropriated to each, with *the same result* of undiscernable deterioration, and *without* manure of any kind, were presented as a still more unequivocal proof that the loss of fertility *does not* occur in every case, as you seemed to assert; since the life of the longest liver in those parts of our State, to which I alluded, had not been long enough to enable him to perceive it, in the instances which I cited. Your assertion, therefore, that deterioration *does take place* in *all* cases, where no alternation of crops is resorted to, seemed to me like taking for granted, that which yet wanted proof. Admit these exceptions to the apparent universality of your doctrine, and I shall think with you, that "were our views mutually understood, there would be no great matter of difference between us." Being sincerely desirous to have my own opinions strengthened by yours, I will now endeavor to ascertain in what that difference (if any,) really consists, by stating my own creed as to rotation of crops: not, I assure you, because I deem it of the least importance to any body; but because such statement may excite a further discussion by abler hands than myself, of a subject highly important to all our brethren, and may thus possibly lead them to perceive, that heretofore they have taken for granted, and accordingly asserted, many things in regard to it, which have never yet been satisfactorily proved; just as in our school boy days, when scanning our Latin lessons, we used to tell our masters that such and such syllables were long or short "*by authority*." Now, although such a reason—if it can be called one, may suffice in lieu of a better, for school boys scanning Latin poetry, I cannot deem it admissible among men who are earnestly seeking the truth in regard to the soundness and utility of any thing recommended to them as a practical rule. Such a thing, unless sustained by well authenticated facts, should never be regarded in any other light, even when most attractively presented, but that of an ingenious and plausible theory. In *this* light, I confess, (perhaps to my future shame,) that I view many of the alleged benefits of our popular rotation systems. Not one of them, in my opinion, actually *improves land*, unless, as I said before, some one or more crops of the course be returned to it, or unless manure, which cannot properly be called a crop, be applied between them. Their food being derived in part from the soil, and in part from the atmosphere, unless the former gets back more than she imparted of the principles of fertility, deterioration must occur in a degree more or less rapid in proportion to the quantities of food required by each crop to bring it to perfection. The few apparent exceptions I have stated cannot invalidate this doctrine, as a general one, and therefore ought not to encourage us to neglect it entirely. I gave them only to prove that it did not hold good in all cases whatever, since in some it was imperceptible. But some plants require much less food than others, consequently when *they* constitute the chief crops of a rotation, deterioration advances more slowly, and this is often called an *improving course;* when in fact, it only *retards* that injury, which would be too visible to be overlooked, if the whole or the greater part of the alternating crops consisted of those plants which require most food. *To retard impoverishment therefore*, is all the credit I think due to any rotation whatever, if all the crops which constitute the course, were taken from the land. Could this opinion be adopted by all our brethren, it would certainly, I believe, have the very salutary effect of causing the whole of our fraternity to pay much more attention to procuring manure than they ever have done; for they would all be convinced that *mere* rotation could do no more for our arable lands than I have stated.

And now, my good sir, before I conclude, let me endeavor to answer the few questions you have asked relative to our poor old mother, Virginia! By the way, they remind me very much of a highly esteemed friend, long since dead, who used to be vastly fond of this Socratic mode of argument, by which he seemed always to calculate on so "penning" a fellow, as it were "in a corner," that there was no escape but to cry out "*peccavi*."

It made no odds to him whether you answered "aye," or "no," he had you either way, with conclusions to suit his purpose.

Your first question is: "have not successive crops of wheat, of corn, or of tobacco, greatly deteriorated some of her once fertile soils?" and your second is "like unto it." It is: "have they not reduced thousands and tens of thousands of her good acres to comparative sterility, to unproductive commons?" To both I reply, that we have, alas! *hundreds of thousands* of once good acres, long ago reduced to "comparative sterility," but not to "unproductive commons;" for they still produce what we call hen-grass, broom-straw, and ever and anon, a starveling pine or cedar bush—the reproachful and melancholy mementoes of ancestral improvidence. But the successive crops to which you ascribe this, are far from being the *only* or the chief cause of this lamentable fact. From the first settlement of the country, until within a few years past, the most deadly enemies to good husbandry in Virginia, have been, *the utter neglect of it, as a science—the implicit adoption, by each successive generation, of the practices of their forefathers; the almost total neglect of manures except for grardens; the incessant alternate cropping and grazing our lands without rest; the culture of them in a certain rotation of workings, without due regard to the condition of the soil as to wetness or dryness.* But *above all*, to the proprietors of this goodly soil generally using it more as the means of gratifying their appetites, their love of show, and the means of displaying it, than sources of future comfort, respectability and happiness to their children, as well as of credit and honor to their native State. The acme of ambition, in the olden times, seemed to be, who should have the best cheer and the most company to consume it, with little or no regard to the "material" of which it was composed, provided these "Nati consumare funges" were lovers *of*, and tolerable contributors *to*, fun and frolic. As long as the plantations held out in furnishing the means of this ruinously merry career, the troublesome study and practice of good husbandry were postponed, like the study and practice of religion, "*to a more convenient season.*" This sir, I sincerely believe, is a true and just explanation of the complicated causes which have contributed to impoverish a vast proportion of our lands, and much to my shame and sorrow have I given it. But I have the consolation to feel assured, that the dawn of a much better state of things, at least in regard to husbandry, is now shining in almost every part of our old State. I fear to inquire how much is owing to the absolute necessity of reform, how much to motives every way laudable, and shall therefore content myself with the fact. There is, however, *one* cause of the happy change with us, in regard to the efficiency of which I feel so perfectly confident, that I cannot omit to mention it. This is, the circulation among us of our friend Ruffin's Farmers' Register and your Cultivator, which have done more than every thing else towards it. Both are read by great numbers of our brethren, and have greatly contributed to awaken them to a true sense of the vast losses they have sustained by their long and destructive neglect of the study and practice of agriculture. That you may both succeed to the utmost extent of your patriotic plans, is the sincere, the constant wish of, dear sir, yours with esteem,

JAMES M. GARNETT.

P. S. Had I not already given you and your readers so heavy a dose of my scepticism, as to fear to increase it, at present, I should here have offered numerous facts, which I have been more than twenty years in collecting, to disprove the doctrine stated in your November number, from Professor Low, that "it is best to bury manure."

Peat Earth, Peat Ashes, &c.

Wheat-Sheaf Farm, Staten Island, Jan. 18, 1839.

J. Buel, Esq.—Dear Sir—In your number of this month, page 191, your correspondent B. in noticing "a recently published account of the proceedings of the British Association for the advancement of Science," as to the improvement of peat bogs, and the use of peat moss or turf as a manure, speaks of the preparation of the latter *in barn yards*, and of *expelling from* the turf, through that mode of preparing it, the qualities with which it is imbued, when taken from the swamps, *deleterious to vegetation.* I began, some months ago the use of it, in some degree, after the modes adverted to by the members of the association; and have, from information I have been able to obtain from emigrants and my own observation and reading, been led to a series of experiments with it. The results I heretofore promised to your columns. Though not even yet as complete as I hope eventually to make them, I apprehend what I have thus far observed may be useful. I apply the turf in a variety of ways:—First, after the mode of preparing it *in compost*, directed by Lord Meadowbanks, "which was printed and distributed gratis among the Scotch peasantry, *many years ago*, and which has *ever since* been highly approved of both by practical and scientific cultivators," in Scotland, Ireland, and generally in all the European countries in which peat is to be found.—That method has been described in former numbers of your excellent publication, and will be found in all its essential particulars in Fessenden's New-England Farmer and Rural Economist, pages 209 to 212, and in Loudon's Encyclopædia of Agriculture. Composts have been made by me which, when made in strict conformity to those directions, have fully justified them. Through that medium, there is no difficulty in *trebling or fourfolding an ordinary farm supply of manure*, and which may (as the authors say,) "be used *weight for weight* as farm-yard manure, and will be found *in a course of cropping* fully to stand the comparison." Whenever I have deviated from the track laid down, I have found that the more strict pursuit of the old practice was the better, and have returned to it. In particular, I find the necessity not only of avoiding the compression of the compost heap by the tread of the men or cattle employed, but the expediency of throwing into it every vegetable material which may contribute to keep it light, and as springy as possible. I also find it most prudent to avoid compression by raising the heap above the allotted height.

My supply of turf to this time, has been taken from a swamp about five feet deep, of about two-thirds of an acre, one-half of which, down to the clay subsoil, I have used in composts or otherwise, and which I propose tilling the coming summer. I have also used the turf in *bottoming* my barn and cattle yard, stables and hog sties, and in burning it for ashes. My first application of it to manuring began with the last spring.

The ashes were used, as I have already stated in a previous number, and I can assure you my clover and grass crops fully justified all the anticipations I was authorized to make. Some of my neighbors, of excellent practical information in ordinary matters, attempted to dissuade me from the use of it. A few days before my harvest, I asked them to call and see a result I wished to exhibit to them. Leading them to a stand a short distance from a field to which the ashes had been applied, I pointed their attention to a very visible line, which could be traced across a part of the field, and asked them if they could perceive a difference on its two sides? Admitting it, I asked them to accompany me to it, and to follow the line across the field, observing to them, that for the wheat crop of the preceding fall, the manuring on both sides of the line, and the seeding for wheat, for timothy, and for clover had been precisely similar—but in the spring, an application had been made to the field to improve the grass, which was found not to be sufficient for the whole field, and had become exhausted on the land at which the line was visible. On examining the course of the whole line, the clover on the side to which the ashes had been applied, even to the last cast of the shovel, was nearly double the heighth and luxuriance of the other, and far better loaded with blossoms; and here, I said, my friend, is the line up to which my turf ashes, of which you disadvised the use, have been applied. Fortunately in spreading, it run out on this land, and thus has afforded me an opportunity of again advising with you as to its usefulness.

My mode of burning, you also have heretofore described, and my experience has convinced me of the policy of smothering the fire, and burning the turf as slowly, and confining as much of the smoke during the combustion as possible. My heaps are generally four to six weeks in burning. That the turf is *purely vegetable* will be perceived from the fact, that *twenty* cart loads of turf are necessary to produce *one* of ashes. Sand or clay are not destructible by combustion, and would, if present, have been found still the same in bulk, and visible to the eye; none however can be discovered in the ashes; and this may be considered as a fair method of testing the question as to how much of mossy earth the turf contains.

Your correspondent B. in your last number queries as to the application of sulphuric acid for converting turf into manure, and for fertilizing a turf soil. This induces me to call attention to facts which have ever been witnessed by me—around almost every opening of the heap, through which the smoke issues, an oily substance resembling sulphur will be perceived. Bottoming before covering them with litter, the shelters, under my barn and sheds, as I always do, to the height of about twelve inches with turf, in order that it may absorb the stale and moisture of the place, I have observed that, though the turf, when taken there dry from the swamp, is perfectly devoid of all smell; after having thus used it, it becomes as *sensibly acid* to the smell, as the most sour lemon. In turning it over, the acid exhalation cannot but be perceptible to every bystander.

All writers upon turf, in speaking of its antisceptic properties, say it is imbued with a phosphoric acid, having some affinity to gallic acid or tannin, and which renders it, in that state, anti-putrescent, and consequently deleterious to vegetation. It will dry rot and pulverize, when exposed to the air, and is in that state pernicious, because it has not gone through the fermentation necessary to render it soluble, and fitting food for plants. The *fermentative* decay and solution of vegetable and animal substances, afford to vegetation its proper nutriment. The turf, it will be perceived, when used in compost, and in contact with fermentative manures, *attracts to itself and absorbs* so much of the putrescent exhalations as is necessary to expel the acid which checks its decay, and to superinduce, as a consequence, its own fermentation and decay, in common with the manure placed in juxtaposition with it. If this then be a tendencency of the turf in the compost, *why should it not operate similarly*, though in a lesser degree, *in the earth* to which the turf is applied, and so far from affording nutriment to surrounding vegetation, attract it to itself, and absorb the putrescent or fermentative substances already in the soil? In the first instance, it was always said, and is no doubt true, that the turf, while saturated with the acid, is deleterious to vegetable growth and to the soil—remotely, and after having, within the soil, taken to itself what will promote its decay, it probably gives it back, and does become in some degree beneficial as a manure. It well may be that sulphuric acid will, by its action on the turf, accelerate the souring to which I have adverted, and thus promote the decay of the turf. Turf was, for a long while, the source of disappointment as a manure, until the principles applied to it by Lord Meadowbanks, were scientifically explained and brought into practice.

In the spring and in the fall, immediately after carrying out the supply of manure from my cattle yards and hog sties, I bottom them anew with turf to the depth of at least a foot, covering it with six inches of sea-weed or drift. To the accumulation of the place, during the rigors of the winter, and when little is to be lost, in fermentative manures, by solar heat or evaporation, I cart around the yard and spread *on its upper edges*, some eigh ten or more feet wide, the emptyings of my stables and yard sheds, with the littered surface occasionally of my hog pens, (which are placed in the centre of my barn-yard.) The feeding racks and moveable pens are from time to time shifted, that the turf and sea-weed may, by the tread and droppings of the cattle, and the occasional moisture of the yard, be worked together, and the turf saturated with them as much as practicable. The main part of the manure, being placed on the upper sides of the yard, in settling down to the centre, and towards the barn-yard drain, passes necessarily through the bottoms of the turf and sea-weed, which thus becomes imbued with the substances necessary to prepare them for the fermentative decay, which the acid of the one, and the saline impregnation of the other, require for them. In the spring, as soon as solar heat may induce a tendency to fermentation, and consequent evaporation and loss, the yards are turned over with a plough or the shovel, that the whole may be so commingled that the turf may attract and absorb the waste which would otherwise ensue. At the lowest part of the barn-yard, and that to which every thing from the farm house, kitchens, and farming yards, and stables tends, I have a cemented cistern, *or tank*, capable of containing 250 hogsheads. The wind-mill and horse-power of the yard is connected with this tank, by pulleys, straps, and chain buckets, so that if during the winter, spring, or summer, I think best to wet my compost heaps, hog-sties, or any of the yards with those drainings, the power is conveniently applied, and by leaders, the draining is thrown back to settle again through the mass and return to the tank. The compost yard adjoins without the barn yard—is so graded that if the drainings from the tank is thrown on to the heaps, after settling through, they return by box underdrains, into the yards and tank. If a surplus is still on hand, a cart, a hogshead and sprinkler is used, with which, in a four to one diluted state, I irrigate such grass lands as I think may be benefited by it, or my grain crops, in such parts of a field as I apprehend may want it—an excellent method of readily adding to the manure, and of forcing those parts of a field which in the spring are perceived to want manuring—or my garden is fertilized and forced with it, to any state of fertility which can be effected by such an application of the stringent and most prompt in its influence of all manures. The last spring, in spots where my wheat did not thrive comparatively, applying it with a watering pot, the grain advanced and outstripped the surrounding parts of the crop, which before had afforded better promise of thrift. Pouring a pint of it into a hill of corn, of potatoes, or of vines of any kind, will be found to give an astonishing impulse to them.

The filling and driving of the cart—of sprinkling it on the field, or applying it to the hill or garden, is the work of the barn yard power, a boy, horse, cart, sprinkler and watering pot. The cart and its sprinkler, in its form and use, is in all respects like those in use in cities for sprinkling the streets. To irrigate and manure drilled crops, the sprinkler should be taken from the rear of the cart, and two of them should be hung parallel with the shafts and over the drills.

During the heavy rains of the fall and spring, should the drainings of the yard accumulate and fill the tank, and not be otherwise wanted, the surplus is let off into a *muck road* embanked on the sides and filled to the depth of ten to fifteen inches with sea-weed, turf, turf-ashes and a small supply of manure, and made gradually to percolate and settle downwards, through a distance of from four to six hundred feet in length, and twenty in breadth, and through which *muck road* cattle, carts and vehicles of every kind, when *it is not too wet*, are forced to find their way, the better to commingle and break up together its contents with the drainings of the barn yard. Until the drainings of the yards have reached the farthest extent of this road, they must escape from applications to agricultural uses. Before driving my cattle from my yards, if it becomes necessary to do so, and always two or three times a day, when its surface is moist, a boy, as a standing order and practice, drives them for exercise several times around the yards, the better to bring the manure in contact with the bottomings. I have other modes, not here explained, by which I readily avoid the access to my yards and tank, of the excess of drenching rains, when storms are heavy and of long duration. This I may explain, if desirable, on another occasion. Within *the last year*, I have lost none—*absolutely none!*—of the leeching of my yards and stables.

To this it will be said by some, it is *laborious and expensive.* Not so much so as may be apprehended, or as would occur with others not assisted with mechanical powers and under-drains, as I am; but what I have thus done at some expense, others may do in a great degree at a mere trifle of expense, and in a way that I may hereafter suggest.

I assume, as a standard, the fact that farmers with us pay 8s. per load for manure, and that is a criterion by which to form an estimate of the labor or capital which may *profitably* be bestowed in obtaining it as I do. If that be the true criterion for judging, every day's labor I expend in producing it, is worth *twenty fold* the sum I pay my hands to effect it.

Turf affords an *incalculable medium for saving the waste of manure*, and for increasing its amount and usefulness, and is better than rich mould, earths, or the pearings and bottoms of ditches, in this—that it is *all* vegetable, and in itself, strictly speaking, a manure, when properly prepared.

The contents of stables, barn yards, and cattle and hog pens should never be exposed to the solar heat, or to fermentative evaporations, or its drainings lost, when turf, or any inert vegetable substance, or surplus farm materials of a vegetable or animal nature abound; nor should animal substances, fish or any other, be suffered to waste their effluvia in the air, when such materials can be had. Enough out of the soil, for all useful purposes, of the agricultural influence or effect of manure is produced *as soon as vegetable or animal decay is sure to progress.* From that moment, a compost should be resorted to, and the heat and action of the manure (which is sure and irresistibly powerful,) be brought to act on substances to which this propensity has not been sufficiently imparted. In this state, all that is ordinarily wasted acts to a useful result in augmenting the mass—and it will be perceived, on referring their ideas as to all fermentative manure, to the principles of Lord Meadowbanks as to turf, that they are far more beneficial as to their substances, not so strongly resisting putrescent decay.

It is a common practice to bury fish, preparatory to their use as a manure, in common raw earth. The most soluble of ordinary manures, it is soon dissipated by atmospheric action, and leaves on the soil to which it has been applied, a raw earth in its then condition injurious to it. I find it far more beneficial to bury the fish in turf and in turf ashes, seven loads to one of fish, (in Loudon it is said, of turf alône, even 20 to 1,) which the decay of the fish will make an excellent and very powerful manure, and one which will endure long after the fish will have done their office in the soil and disappeared.

But I perceive I am making my letter so long as to trespass on your columns, and will stop, only adding, publish all, or such parts of it as you please, and if you desire it, more anon. Yours very truly,

W. W. SEELY.

☞We do desire "more anon."—*Cond.*

Carrot and Ruta Baga Culture.

Richland, Oswego co. Jan. 22, 1839.

J. Buel—Dear Sir—Agreeable to your request, I send you a few lines, describing my method of cultivating the carrot and ruta baga. My opinion in regard to profit, is in favor of the carrot. As to the relative value, I have entertained the opinion, that the same weight of carrots is worth, for stock, nearly double that of the ruta baga. I fed my work horses on carrots, from November, 1836, till June, 1837, three span; they remained in good plight, and performed as much as I ever had any within that length of time—they ate no grain—nothing but hay and carrots, thrown whole into the manger. I have raised one thousand bushels of carrots or over, yearly, for three years past, on an acre of land.

In 1836, I raised between two and three thousand bushels of ruta bagas. They produced from six to seven hundred bushels to the acre. They grew very large—the largest one weighed 30½ pounds. The land was stony and gravelly, made mellow and ridged high with the plough, two and a half feet or over apart from centre to centre. The seed was planted about the 10th of June, which I found to be late enough. Method of planting—one man goes forward with the hoe and makes marks for the seed, in the centre of the ridges, about twenty inches apart, which is very quick done, nearly as fast as a man would walk; another man follows as fast with the seed, and drops from four to five seeds into the place with his thumb and fore finger, and covers the seeds at the same instant, with the remaining three fingers. In this way I think a smart man would drop the seeds and cover two acres a day.

The same year, 1836, I raised one acre of carrots, which produced over one thousand bushels. I measured one rod of the ground, where the carrots appeared to be the best—the produce of this rod was at the rate of over fifteen hundred bushels per acre. Multitudes of carrots from this acre measured four and five inches in diameter at the but—the longest one that we found measured over two feet. The soil was deep, gravelly and stony, originally covered with large sugar maple, interspersed with large hass and hemlock. I cannot admit that the whole expense of labor on the one acre of carrots, including the harvesting, was over thirty or thirty-five dollars. The land on which they grew had been occupied the year previous with carrots, potatoes, corn, ruta bagas, beans, and other garden sauce, and manured with long manure on the one half, and hog manure on the other. Between the 1st and 5th of May, (it having been previously deeply ploughed,) I commenced work in the morning with six or seven men and boys, three horse team ploughs and harrows; at 12 o'clock, M. the same day, the planting was finished. I have no douht that Judge Buel, had he been present, would have considered the planting of the seeds to have been slightly done, but the crop was a good one, being one thousand bushels or over per acre. First we ploughed the ground very deep, and harrowed the furrows level; then took each man his hoe, reversing the edge of it, and expeditiously scraping or dragging the hoe along the surface of the ground twenty or twenty-four inches apart, bearing on the hoe sufficient to make a large mark or track, and to remove the stone and other incumbrances from the track or drill; and so on back and forth until the whole acre was marked out in drills;—then each man or boy took a small dish with seed in one hand, and stooping down so as to bring the other hand as near the ground as may be, to prevent the wind from blowing the seeds out of their place—walking quick-step, each one strewing the seeds according to their own good judgment—having previously received a good lecture from the master not to strew the seeds too thick. When this was done, each man took the hoe again, and half reversing it with the edge up, went through again with an increased movement, gently puddling or stirring the soil in the centre of the drills. A piece of board or stick four or five feet in length, will answer this last purpose about as well as a hoe. A great part of the seed sown by some farmers, is lost by deep covering. A shower of rain will fetch them up without any covering, where the soil is loose and well fitted. The ground between the drills ought to be brushed over with the hoe immediately after they begin to come up, or before, if you can see where the drills are, so that you can avoid disturbing the carrots.

I think a man may cultivate three acres of carrots with the same amount of expense and labor, by keeping in advance of the weeds, as he can one acre in the common way, with the weeds in advance of him a number of days. When the carrots get up ten or twelve inches high, I plough betweeen the rows with a horse, again and again. When I harvest them, I run a strong team and plough as near the out-side rows as possible, and very deep, turning the furrow from the rows; the hands follow after, and pull them out by the tops with ease, a number at once, and throw them in heaps; and so I proceed until the piece is finished. If there was any difference in the crop, it was in favor of that part where the long manure was spread the year before. I planted the same piece, in 1837, without any additional manure. The crop was about one-quarter less. I have no doubt that it would be a great benefit to our farmers who keep stock to cultivate the carrot, especially for milch cows. To those who are not experienced in the cultivation of the carrot, I would say, sow your seeds in drills, at least twenty or twenty-four inches apart; the earlier in the season the better, if your land is in good order; if they stand thin in the drills, they will be large; if very thick, it will spoil the crop. Respectfully yours,

THOMAS S. MEACHAM.

Horse Harness.

Canaan Centre, January 15th, 1839.

Sir—The object of this communication is to call the attention of farmers to the inconvenience and needless expense they incur in using the kind of harness, for their common business, at present mostly in use among them. We are too much the slaves of fashion; and instead of studying economy, or our own convenience, in endeavoring to keep pace with the rich, or those in higher or different situations in life, we are often found with articles of dress or equipage, far from being convenient for our business or appropriate to our condition. It probably does not occur to many, that the harness used fifteen or twenty years ago, was more convenient, less expensive, and more enduring than that mostly used at the present day; being calculated for business instead of pleasure. The most objectionable part of the harness now used is the breeching, which was never calculated for heavy loads, and is very unsuitable; horses not being able to back or hold a load with half the ease as with those of the fashion of by gone days. The fashion of the breeching now in use, was introduced into this country from England, some forty years ago, and was called the phæton breeching; the name indicating an article for pleasure rather than convenience, yet we have almost universally adopted it for all kinds of heavy work. The Pennsylvania, or Dutch breeching, is far cheaper on account of its durability, than the phæton, and far better adapted to the ease and convenience of the horse in any situation. Martingals, gags and checks, are also very objectionable for a business harness; tending to confine a horse to one position, and of course curtailing the free use of some of his muscles; and requiring greater exertion in others, adding much to the performance of what is required of him. It appears to me, that it will require no logical demonstration to convince any reflecting mind, that where great muscular exertion is required, a free and unfettered use of all the muscles, as far as circumstances will admit, is very important. The cheapest, most convenient, and durable harness, is made with leather tugs from the hame to the hind flank, about three feet long; with a ring in the end. Pennsylvania breeching, with a leather strap from the ring of that to the one in the end of the tug. Chain traces, with what is called a T, on one end, which goes in at the ring on the end of the tug. Whiffletrees, with rings at the ends, the traces passing through them and hooking to any required length. Scotch collars, iron bails to hold back, and wire snaps on the lines. Many farmers suffer much by neglecting to oil their harness seasonably and properly; though once a year, if done as it should be, is generally sufficient. The best way is, after the harness is taken to pieces and cleaned, to have a kettle of warm water and put your oil into that; then dip in one strap at a time, taking care to let the oil close up to the strap as you take it out. It will then require rubbing off with a dry cloth, and will remain soft for a year. The water should not be so hot as to scald the leather. Neats or pigs foot oil is the best; next to that, fresh butter if you can afford it, if not, hogs lard. Many farmers suppose nothing so good as curriers oil, but that should be the last used. Harness not used for a year or two, is greatly injured by becoming hard and cracking; for that reason, a new harness lying idle for any considerable length of time, is not worth as much as one carefully used the same length of time. Yours respectfully.

DANIEL S. CURTIS.

Corn Crop.

Trenton, Oneida County, January, 1839.

Judge Buel—Sir—Enclosed I send you a statement of a piece of corn and potatoes raised by me this season, which I offer for a premium, tilled according to the directions of your valuable paper. I hired two acres, (not owning any myself,) of old meadow land, for two years at $6 the year per acre, with what manure I wished to draw on it. The soil is a strong gravel. I drew on manure two days, about 28 loads of the coarsest I could get in the yard; some of it dry straw, and spread it even. I ploughed, rolled and dragged it well, and marked it out three feet each way, in fine order, and planted on the 17th of May three hundred rods with eight and twelve rowed yellow corn, six and eight kernels in a hill, the seed dry; the remainder I planted with pink eyed potatoes. When the corn came up I put on sixteen bushels of lime-kiln ashes; in a few days I run the cultivator through both ways and commenced hoeing; as soon as the hoeing was finished I put on two hundred of plaster; the second hoeing soon followed the first, when the plants were thinned to four in the hill. I intended to give it a third hoeing, but the corn was so rank and stout I could not get through without damage to the crop. The hoeing was done well and the surface left as level as possible. The potatoes were hoed at the same time and hilled. I gathered ten bushels of seed corn the last of August, which was dry and hard. I cut up, shocked, husked and housed my corn and stalks in September. My stalks are bright, and much better fodder than hay. I have enough, I think, to winter two cows. My corn is all sound and hard; the product of the two acres is,

10 bushels of seed corn, worth $2 per bushel,.		$20 00
161 bushels market corn, weighing 61½ lbs. the bushel, sold for $1 per bushel,...........		161 00
23 bushels of nubbins fed to hogs, worth 87½ cents per bushel,........................		20 13
40 bushels potatoes worth 31 cents per bushel,		12 40
1700 bundles of stalks,......................		16 00
500 pumpkins,.............................		5 00
Value of whole crop,....................		$234 53
EXPENSE OF WHOLE CROP.		
Use of land, ...		$12 00
Drawing manure two days, ...		4 00
Ploughing land,................................		5 00
Rolling, dragging and marking, ...		2 50
Planting, three days, ...		2 25
16 bushels lime kiln ashes,..................		1 60
Putting on ashes,............................		75
Horse and hand with cultivator, three and one fourth days,................................		3 25
First hoeing, six days,........................		4 50
200 lbs. plaster,............................		50
Second hoeing, four days,....................		3 00
Cutting up and shocking corn six days,........		4 50
Husking, twelve days,........................		9 00
Houseing stalks,.............................		1 00
Digging potatoes,............................		1 13
Thrashing corn, ...		3 00
Expenses of whole crop, ...		$57 98
Value of one acre,.................	$117 26½	
Expense of one acre,...............	28 99	
Nett profit of one acre,..........	$88 27½	

JAMES PARKER, Jr.

I hereby certify that I am personally acquainted with the above named James Parker, jr., and believe him to be a person of veracity, and that the truth of his statement may be depended upon.

WHEELER NEWTON, *Justice.*

From my own observation of the above mentioned crop, I consider the above statement correct.

NATHAN COB, *Justice.*

Corn Crop.

J. Buel, Esq.—Dear Sir—I send you a statement of the expense and product of one acre of ground, planted with Indian corn, the small eight rowed yellow variety, together with the mode of cultivation.

Soil and Culture.—The soil a sandy loam, ploughed the first day of May. Sward, which was timothy, and mowed the summer previous, laid flat though not deep; then carried on thirty wagon loads of unfermented manure, rolled and harrowed the ground well, without disturbing the sod. On the 12th and 14th planted the corn, two and a half feet between the rows, and sixteen to eighteen inches between the hills; seed simply wet and plastered; ashed when it first made its appearance; hoed the 11th June, and again dressed with ashes. About the middle of July hoed it the last time, making two hoeings, without hilling the dirt up around the corn any, or but a very little.

Harvesting.—Corn cut up about the middle of September, and shocked in small shocks; the first of October husked and measured.

Product.—Seventy-seven bushels sound corn, and five bushels pig or poorish corn, that grew on the suckers, for they were not taken off, as I did the year before, because my corn stood rather unsound from the fact that it was partly covered by a hired man.

EXPENSES.		
One day ploughing and boarding,.............		$2 00
Rolling and harrowing, one day,..............		2 00
Seed and plaster, ...		0 75
Planting, two days, ...		1 50
Hoeing, three days, ...		2 25
Horse and hand, two days,....................		2 00
Cutting and shocking,.........................		0 75
Husking and housing,.........................		6 00
Ten bushels ashes at one shilling, ...		1 25
Interest on land,..............................		3 50
Thirty loads manure, ...	$7 50	
Carting and spreading,................	7 75	
	$15 25	
Deduct for succeeding crops in rotation,	10 00	
		5 25
Total charges,.............................		$27 25
VALUE OF PRODUCT.		
30 bushels seed corn,.........................		$60 00
47 bushels sound corn,.......................		47 00
5 bushels of pig corn, ...		2 50
4 loads stalks,..............................		8 00
2 loads pumpkins, ...		2 00
		$119 50
Deduct expenses,..........................		27 25
Nett profits,................................		$92 25

HENRY HOPKINS.

I hereby certify that I am personally acquainted with the above named Henry Hopkins; believe him to be a person of veracity, and that the truth of his statement may be depended on.

HARVEY BUTTS, *Justice.*

Laurens, Otsego Co., N. Y. Jan. 15th, 1839.

Morus Multicaulis.

Judge Buel—Sir—Since our communication to you in September last, on the subject of mulberry cultivation and silk growing, we have received addresses from nine different states and several from each state. All these give credit to the columns of the Cultivator, as the organ through which they were informed of our location and business, and many other addresses from the same states, have given equal credit to the Genesee Farmer.

These addresses in general, appear to have originated with men of science, property, talents and enterprize. And considering these a criterion of the hundred addresses received by yourself and others on this subject, it is a sufficient guarantee for us to conclude, that, this business being in such hands, the most skeptical need have no fears of its ultimate success.

For our own part, we are fully satisfied that the silk culture will progress with those who are qualified to appreciate its worth—but to make it more general as an acquisition to the state, it needs legislative aid.

We are therefore, strongly impressed with the opinion, that our legislature will not be last or least in its encouragement to this national movement.

We hazard nothing in saying, there is no agricultural project or domestic enterprize, which appears so feasible and promises so much to the American nation, as the cultivation of the mulberry and raising the silkworm.

A number of our correspondents have solicited from us, our manner of cultivating the mulberry; the best kinds of earth, inclination, &c.

We are young in this cultivation in comparison with some others, but having succeeded fortunately in the little we have done, we cheerfully give a partial synopsis of our former practice and future intention.

We have had but one location, and that a little elevated; has a southeasterly inclination, soil a sandy loam.

We prepare the ground for trees the same as for corn—furrows six feet apart sufficiently deep to receive the roots of the trees; lay the trees in the furrows, roots the lowest, making the most natural disposition of them we can, in this almost horizontal manner cover the roots and pack the dirt around them singly—cover the trunk and limbs about an inch and a half to two inches deep, leaving a hollow in the furrow to fill up after the buds have vegetated sufficient to want hoeing.

For layers or cuttings, prepare a bed as for onions, and for layers mark off drills from three to four feet apart; lay the limbs in these drills, cover from one and a half to two inches.

For cuttings make the rows from two to three feet apart, sticking down the cutting from one to one and a half feet in the row, place the cutting in an oblique direction—inclination to the north—angle about 45 degrees—upper bud on the north side of the cutting, a little below the surface.

For one bud cuttings, pursue the same course as with the upper bud of the second bud cuttings, crowding it a trifle deeper.

Water all at evening, according to circumstances, sufficient to retain a rational moisture that would be proper for other vegetables.

We intend removing to Long Island, near New-York, as soon as navigation will permit after the first of March. All communications, therefore, addressed to us, after the opening of the navigation, should be directed to Brooklyn, Kings county, Long Island. Yours with respect.

S. E. GIBBS & SON.

Troy, Feb. 11, 1839.

Multicaulis.

Coxsackie, N. Y. January 30, 1839.

Mr. Buel—Sir—Permit me to suggest to you my views as regards the Morus Multicaulis mulberry. I have noticed in your publications, at different times, remarks upon them, and representing them as being too tender for our climate, and freezing to the ground in winter. In this I am ready to agree with you, from the experience I have had in them for the last four years. Yet there are good qualities in them, which ought not to be forgotten; and such as stimulate every one who expects to make silk to propagate them. I do not consider their freezing to the ground any objection; as the roots do not freeze; but they shoot forth a greater number of sprouts, and bear larger leaves than older trees, and are more convenient for gathering, as a person may stand upon the ground to gather them. I think these and other advantages they have over the white mulberry, are sufficient to encourage all to propagate them. In this way they may be propagated in hedges or rows, and if the sprouts are wanted to propagate from, they may be cut to the ground every fall without injury. Of the few I have cultivated for the last four years, I have lost but one root. Yours with respect,

W. S. JACKS.

The Bur Oak.

Lake C. H. Ia. Jan. 25, 1839.

J. Buel, Esq.—Dear Sir—Your note of the 31st. ult. is received. I shall send a box or bunch of the Bur oak acorns to you for your own use and distribution, at the first opening of navigation in the spring. If they will grow, I shall feel proud of having introduced a new variety of tree, and a good one, into your section of country. The tree requires a very strong soil. I am now using in my family, pork fatted upon the Bur oak acorns, which is to all appearance as good as corn fed, except it is more dry and less inclined to fry out much fat. The timber, too, when seasoned, is the most solid and strong of all oaks. The tree, when in foliage, is one of the most beautiful in the forest, though it does not grow commonly in "thick timber;" but it is found covering very large tracts of land called "barrens," an intermedium between prairie and timber; after growing so isolated as to have the appearance of a scattering orchard and having a strong resemblance to the work of man. You may travel miles before the country is settled, through these "barrens" with a carriage, without any obstruction. In these barrens the trees never grow large—the soil being deep, the roots are situate so far below the surface that they offer no obstruction to the plough, and these barrens are often ploughed without removing the timber. I remain your friend truly.

SOLON ROBINSON.

School Libraries.

The introduction of libraries into our common schools is becoming daily, a subject of deep interest. Among the libraries presented to our notice, is one selected and prepared by the American Sunday School Union, of which we have only space now to say, that it consists of one hundred and twenty-one volumes, on a variety of subjects; neatly printed and bound, accompanied with fifty descriptive catalogues, and the whole contained in a substantial case, at the low price of thirty-three dollars.

That a highly beneficial influence may be obtained over the minds of the rising generation, through the medium of good books, is beyond doubt, and every one will see the propriety of our urging upon those who are empowered to procure libraries in their respective districts, that they be careful in their selections. We commend to their notice the above mentioned library.

They may be procured of Mr. E. H. Pease, No. 82, State-street.

M.

Note.—We give the above, as we received it, without meaning to adopt its sentiments. We have yet seen no catalogue of a common school library, that we felt willing to recommend for that purpose; not on account of what it *does* contain, but of what it *does not* contain.—*Cond.*

Hints to Silk Growers.

From a Female Correspondent.

Sir—Some years since I was an inmate of a house where the mistress was engaged in the cultivation of silk; without having any fancy for the employment, I became curious on the subject of its introduction ininto this country, as a new branch of industry. I read whatever I could find upon the subject; among other things, Arthur Young's tour through the silk districts of France, made for the purpose of ascertaining whether it could be introduced into England to advantage. He decided that labor was too valuable in England, and I argued that surely then we could not compete with France, Italy and China.

But in reading an account of the growth of silk in China, I learned that the finest made in that country was grown in the southern provinces, where, from the mildness of the climate, the worms were put out on the trees, and left to feed and provide for themselves agreeable hiding places for their cocoons; upon this circumstance it is observed, that the perfection of spinning greatly depends. For a worm, if not satisfied with its position, will change its location several times, spinning a little in each place, and so wasting and tangling the thread; sometimes, when not very well provided, two or three will insist upon working in the same envelope, and so spoil all their cocoons.

Worms are apt to be injured by heavy rains, hot suns, dews, and loud concussions of thunder.

It therefore occurred to me, that a shed, constructed like a rope-walk, would fully protect hedges of mulberry trees, during the time the worms were out, so as to allow them to be at liberty as they are in the south of China; feeding themselves and selecting their places for spinning. The sheds should have a coarse, cheap roof, divided say every eight feet, each part hung at the top, on strong wooden hinges, upon which it should turn entirely over and hang down on the north side, so that when the cocoons were gathered, the trees might be, for the rest of the year, exposed to the rain and sun, with a shelter from the extreme cold of the north wind. The great interest lately expressed on the subject induces me to make these suggestions, in hope that some one of the many speculators employed in the business may gratify me by making the experiment. Much fewer trees would be necessary than when they are stripped, as a large portion of the leaves are left by the worms, and so wasted; it saves the labor of feeding them, and certainly will be less expensive than taking up the mulberries like cabbages, in the winter.

Respectfully yours, &c. M.

Belmont, Va. January 26.

Inducements for entering on Rural Pursuits.

Mr. Editor—We were pleased to see, in looking over a late number of the Cultivator, a circular addressed to the public, on the subject of an agricultural school. We hail with joy, the establishment of such an institution, and we trust the proposal will meet with such favor from the public, as will enable it to be carried into early operation. It is time something effectual should be lone to remove the flood of ignorance and prejudice that has covered the face of a large portion of the agricultural community, for the last half century. The system of agricultural societies, with annual exhibitions, and the unwearying labors of agricultural periodicals, have undoubtedly accomplished much in raising the character of the farming community, and all praise is due to them for it. But we fear, that without farther aids, their utmost endeavors will fail of the object they have in view; the production of a healthy tone and liberal spirit among our farmers. The strong conservative feeling among farmers generally will still, we fear, as it has in a great degree already, prove too strong for them to cope with single handed. They must be *backed up* by the community at large. This correcting an error here, and an error there, this ousting old systems of culture by the partial introduction of new ones, this union of science with practices in husbandry engendered in ignorance, and established by lapse of years, which is so often attempted, cannot, we believe, produce a thorough going reform. It is too much like healing the sores and plague spots that break out upon the diseased body, without attempting to remove the malady that causes them. The evil must be probed to the bottom. Instead of resting our hopes of success in the regeneration of agriculture, solely upon the issue of a struggle with the fondly cherished errors of a majority of our farmers, we must raise up a race of farmers, who never shall have known such errors, and who, by the aid of science and education applied to agriculture from the very outset, as a regular profession, shall be enabled to look upon the culture of the soil with the respect it deserves, to feel its beauties and see its importance to the whole community as well as to individuals.

We hope to see the many inducements for entering into and making agriculture a regular profession, which presents themselves to the thousands of young men of the present day, who are in doubt as to the calling they shall select, set forth by some abler pen than our own; and that very many will be persuaded to avail themselves of the advantages of such a school, in the event of its establishment, to prepare themselves for an honorable an useful pursuit. If, in the selection of their profession, the desire of contributing the greatest amount of good to the greatest number, enter at all into their consideration, let them think well of an agricultural life, before they decide. Let them remember that the avenues to almost all the other pursuits, mercantile, literary and mechanical, are choked even to their very entrances, and that crowds have already entered them fully able to fill their highest stations, and carry off their honors and emoluments. Let them remember, that while to all other pursuits the all pervading influence of education and science has been fully extended, the agriculture of our country, from the absence of that influence, remains almost where it was a half century ago, and that the discoveries of science can be applied here with as wonderful results as they have been in other professions. The trouble is not that too little is known as to the great principles, that should govern agriculture; but that too few know them. The wants of the farming community do not so much demand new improvements and discoveries, as an increase of those, who by their example and precept, may induce others to adopt what is already known.

The researches and labors of a few have amassed information upon the culture of the soil, sufficient, if properly applied, to cause the whole face of our country, to wear the smiles of a garden; and public interest now calls for those, who by the application of this knowledge in every part of our land, may induce all engaged in agriculture to yield to it, and thus render general its influence. Let those who are in doubt as to the choice of a profession, remember, that in taking up agriculture, they have a wide field for action. From the nature of our country and institutions, we must, to a very considerable degree, be an agricultural people; and, as we have already said, there is no one pursuit, that stands so much in need of the aids of science, and the assistance of men professionally educated for it. If, therefore, they would have their names connected with the best interests of their fellow men, if they are ambitious of a reputation that shall be as lasting as honorable, let them become tillers of the soil, and prepare themselves for the duties of the farmer with the same zest and care that they would bestow upon any of the literary professions. And let them also bear in mind, that in agriculture, as in every thing else, as far as their own individual interests are concerned, their success will be commensurate with the amount of information and degree of application they bestow upon the objects that engage their attention. "*Seges votis respondit.*"

The subject may be presented in a different, and perhaps to some, a more pleasing aspect. We speak without the slightest regard to the fanciful pictures of the poets, of rural pleasures, pretty visions of shepherds and shepherdesses, meandering streams, and lover-like grottoes, &c. &c., when we say, that there is scarcely any pursuit that exerts, in an equal degree with that of the farmer, an elevating and refining influence upon the mind, connected with the most unadulterated pleasure. Removed, as it is, from the contracting effects of business and the corroding influence of political strife, it opens one of the grandest fields for the study and admiration of nature's works. The study of her operations, and a knowledge of the laws that govern her, are pre-eminently necessary for any success in agriculture. And what is more, we deal with animated nature. The smallest plant that grows, as well as the animal that demands our constant care, is endowed with vitality, and while it lasts, presents all the curious and wonderful changes incident to life. The creatures that Providence has made dependant on the farmer's care, all possess an individuality; and we soon learn to study and honor their various characters. Indeed, in every department of agriculture, the educated mind may find ever changing material for study and admiration: is constantly "looking through nature up to nature's God." It deals with subjects beyond the influence of mens' passions and prejudices, and is led daily to perceive the littleness of all things human, compared with the least of God's works.

If there be any then, of those still casting about them, in doubt which of the many avocations to enter, who have a taste for rural pursuits, let them gratify that taste, and believe that in so doing, they will at the same time consult their own interest, and that of the public. Let none, in the consideration of this subject, limit their ideas of agriculture, as is too often done, to the plough-tail and the harrow, and suppose that the farmer's operations extend no farther than to the use of the spade and flail. If they do, they will deceive themselves, and do the subject great injustice. Let them rather, if they have no other means of judging, turn to some educated, liberal and high minded agriculturist, if any such they have among their acquaintances, and take a few lessons from his word and example, before they come to any such conclusion. We believe they will find him enjoying the true "otium cum dignitate," drawing upon nature rather more for his occupation and pleasures; dispensing to those around him these pleasures and the information he has acquired; and, in one word, enjoying that great desideratum of human life, "*Mens sana in sano corpore.*" H. V.

Greenfield, Mass. Jan. 19, 1839.

Light wanted—Corn and Potatoes successfully alternated in culture.

Brooklyn, Susquehannah co. Pa. Dec. 1, 1838.

JESSE BUEL, Esquire—Dear Sir—The agricultural interest is of vital importance, for it is upon this that we wholly depend, being not only the source of our wealth, but the medium of our existence. I have long seen that our citizens are too negligent in their avocations, and do not pay that attention to practical publications upon tillage, which their interests severally demand. We go on too much in our own individual and old way, and seemingly spurning the notion of learning and practising upon the well tried experiments of others. I have long wanted to enjoy the profit of reading the practices of farmers in various sections and latitudes, and upon different soils; and when I cast my eyes about me, my anxiety increases; and I would fondly hope that ere long your Cultivator would be both generally taken and read among us. It is true that many modes of tillage on other soils, and in foreign latitudes, may not be well adapted to our own; yet we know that many times, useful hints are taken from events of a foreign nation which prove to be, on trial, very salutary. Our country is new; our citizens are land clearers; and ere long must be either emigrants or land ploughers and grass growers; and every one must, or ought, to see that the most successful mode of doing these without reducing the fertilizing powers of the soil is an object highly desirable. No question can be raised that the most of us, if not all, by following in the too well beaten way of our predecessors and of superstitious practice, sacrifice not only our labor, but the strength of the soil we cultivate. It is indispensable, then, that we should reform. And how shall we do this successfully without that light which practical experience may shed upon us.

I noticed an experiment in your Cultivator, upon planting corn and potatoes together, by alternating the rows of each, and accordingly I tried the same with a small variation. I planted fifty-four perches of ground, after being once ploughed perfectly and well dragged, in the following manner, viz: three rows of potatoes and three of corn, and thus alternately. The corn I planted in rows, three feet and a half by two feet, with three stalks to the hill; the potatoes, in drills from a foot to fifteen inches asunder; planting both on the flat surface. I planted on the last day of May, and harvested on the 15th of September, and obtained twenty-four bushels of ears of corn, three loads of pumpkins, and fifty-five bushels of potatoes. The season was not altogether congenial to the potato with us last summer, being too dry; of course the seed was, by hoeing, raised too high to insure a full crop; and had the ground been lightly furrowed for the potatoes, and ridged for the corn, I think the produce of each would have been considerably increased—that of the potato in particular. The produce of an acre would have been 71 bushels of corn, and 163 of potatoes. This is at the rate of 35½ bushels of shelled corn to the acre, according to the usual mode of planting: and since 40 bushels in this country is counted a tolerable crop, the potatoes might be counted almost a clear gain to reward for the experiment. S. W. NEWTON.

Caterpillar in Wheat, &c.

Warren, Warren co. Pa. Dec 27, 1838.

J. BUEL, Esq.—Dear Sir—In your October number of the Cultivator, you allude to "A new insect enemy to the wheat crop," and invite a description of a worm, said to prey upon the mature grain. Such an enemy has made its appearance here.

I first noticed a worm in 1837, in a small patch of winter wheat sown in my garden. When the heads had just shown themselves, and before being in blossom, some few of them turned yellow, dead. On examining, I found a worm in the upper joint. When the wheat was at maturity, I found the same worm in the kernel, of larger growth, but they were not numerous. They were examined with a magnifying glass. Those in the joint and those in the kernel were alike except in size. My field wheat also had some few of the same worms. In 1838, I began thrashing my winter wheat immediately after harvest; on cleaning up, was surprised to find in the screenings, separated from the heavier and better part of the wheat, a vast army of the new discovered enemy.

I now thought it might be of importance to examine them with a view to an acquaintance with their habits. It is a caterpillar, about 3-8ths of an inch in length, when full grown—is of a straw colour, but viewed through a magnifier, is striped lengthwise, with orange and cream coloured stripes—its head dark brown. All its movements, shape, legs, &c. indicate the caterpillar, and it will suspend itself by its web. The broken kernels indicate plainly that it preys upon the mature grain. I took a handful of screenings and worms and put them into a clear glass decanter, in September. They were very lively, and would have made their escape, but were prevented. After remaining unmolested for some time, they buried themselves under the wheat, where they seemed satisfied to remain, unless disturbed, when they would again endeavor to make their escape. After two or three weeks, they became languid, and in six weeks they had ceased to show any symptoms of life. I have preserved this sample of wheat for the purpose of examination another summer, if perchance a new generation should succeed.

How extensive the ravages of this worm are, I am not imformed. How much influence it may have had in lessening my own crop, I am not prepared to say, but for some cause the yield, on thrashing, is much less than was anticipated. It may have been noticed by others heretofore, but is new to me.—Perhaps it may be comparatively harmless. The increase however from 1837 to 1838, was immense; and a like increase in future would be attended with calamitous effects. Whether such increase will take place, remains to be seen. The insect described by Mr. Murphy, in your November number, differs from this in colour and in size, and he says he saw nothing in the form of legs—this worm has legs like other caterpillars.

In your June number, you gave place to a communication from me, in which I stated that I had sown two bushels of winter wheat in the spring, after having prepared it as recommended by one of your correspondents, see 4th vol. p. 64. The result was not in favor of repeating the experiment, the crop being very late, light, and inferior in quality.

The Italian spring wheat has succeeded with me the past season, better than winter or other spring varieties. My spring wheat, early sown, was but little affected with the above worm. Very respectfully yours,

NATHANIEL SILL.

The Mulberry—Varieties.

Linnæan Garden and Nurseries,
near New-York, February 4th, 1839.

J. BUEL, Esq.—Dear Sir—Having been applied to by numerous persons to decide whether the Morretti mulberry of France, and the tree called "Alpine," are the same, and it having been controverted by some persons, we now state explicitly, that they are identically the same, and that every tree called Alpine was grown from Morretti seed. A quibble is made by some persons, who say the Alpine trees are *selected* Morretti—but we presume they are quite as much selected when under one name as when under the other. The Canton and Nankin mulberries are also identical with each other.

Of all the varieties of the mulberry ever yet introduced to this country, the Morus Expansa is pre-eminent for a northern climate, as it is very hardy, and has leaves equal to the multicaulis in excellence, and second only to it in size. Yours respectfully,

WM. PRINCE & SONS.

Blight in the Pear-Tree.

Near Vincennes, Ia. 16*th January*, 1839.

J. BUEL, Esq.—Dear Sir—As I have been a subscriber to your Cultivator, except the second year, I will say a word about preserving pear trees, from personal experience.

Pear Trees.—The first was as thick as a man's thigh; limbs and leaves turned black; I cut off all that was dying; continued to cut off all but two side limbs; new shoots put out, and the tree now has a fine top. Second, a small tree with a fine top, all the leaves turned black; I cut the limbs all off to near the body, rubbed the body with soft soap, made strong with lye; in two years after I cut off five shoots, from three to five feet long, leaving four shoots on; I have seen no more black leaves on this tree. Third, a pear tree as large as the calf of a man's leg, the top leaves turned yellow, and the under leaves turned black; I cut out ten feet of the top and all the limbs that had black leaves on them, and rubbed the body with soft soap and lye. Since that time it has grown finely; no more black leaves on any of these trees. Yours respectfully,

DANIEL SMITH.

Fish Manure.

Upper Aquebogue, Suffolk co. L. I. Feb. 1, 1839.

J. BUEL—Dear Sir—Mr. Roberts inquires in your November number, whether fish as a manure will impoverish

land. Now as long as land will produce good crops, it is immaterial whether it be rich or poor, and as long as he uses plenty of fish, with an ordinary blessing, he may rely on good crops. I have used fish manure forty years successfully, and my land is much better than when I first commenced fishing. I make use of from fifty thousand to one hundred and fifty thousand of fish, known here by the name of mossbankers, per annum, and could I get a million I should have none to spare. There is no manure that I use equal to fish for a crop of wheat, and all kinds of roots; but they do not have that effect, after repeating, that they have at first; and that is the case with all kinds of manure. Thence the necessity of mixing manures. Ten thousand mossbankers per acre is sufficient for a crop of wheat, without any other manure. My practice is, to put on twelve or fifteen large wagon loads of litter, and five thousand fish per acre, and then I calculate for a good crop of wheat, and after the wheat a good burthen of grass for three or four years. The same quantity of manure makes a good crop of Indian corn. The manure fishery is the making of the east end of our island. I think I may say that the production of our land is three times as much as it was before we commenced fishing. But it must not all be attributed to fish. We exert every means to make and collect manure, for without it we cannot raise our bread. For a farmer to break up a piece of land, and lay it down poorer than it was at first, is like borrowing money to pay his interest. It is astonishing to me that there are some few farmers yet, who will let their manure lie and ferment in the yard, when they must know that they lose half its virtue, for there is no time that it brings forth vegetation so well as when in a state of fermentation under the sod. I might say that our soil is a sandy loam.
JOHN WELLS.

Relics of by-gone Superstition.

Schenectady, January 10th, 1839.

Dear Sir—Your industry and perseverence have enriched the Cultivator with much useful instruction and advice, both for the cultivation of the fields and the minds of farmers. If they will be wise enough to put them in practice, with as much earnestness and zeal as you have composed and published them, our country will soon exhibit beautiful hills and dales, loaded with agricultural wealth.

But sir, there is a quarter of our horizon yet incumbered with the clouds of ignorance, which if you can clear up and expel, it will redound much to the honor and excellence of christianity, over paganism and error, as well as to the improvement of agriculture.

The last time I sat on a grand jury, a woman of Duanesburgh applied for protection from her neighbors, who called her a witch. They sought opportunities to attack her when passing in the street, and attempted to draw blood from her *head* by striking her, believing that if they were successful, it would protect them from her witchcraft. The grand jury indicted several persons who had thus assaulted her. She was Scotch, and one of the grand jurors who lived near to her, said, that some of her neighbors believed that she had lately made a pass to Scotland, over the ocean *in a wash-tub.*

About three or four years ago, Martin Sitterly, a descendant of German parents, in Rotterdam, adjoining this city, stopped at our store, and said he was on his way to the adjoining town of Glenville, to expel the witches from the cattle of a Dutch farmer there, who had sent for him for that purpose. Shortly after, that farmer stopped at the store, and we attempted to admonish him for such folly. He answered with great pathos, that *when his cows all slunk their calves, it was time to do something for them.* My son asked him if he raised rye on his farm, thrashed it in winter, when his cows came about the barn doors, and eat the talings, or winnowings of the rye? He answered in the affirmative. We then told him, that the spur or ergot in the rye, which was eaten by the cows, caused them to lose their calves, and not the witches.

If grand juries would indict, and the courts would condemn to be hanged those convicted of witchcraft, as they formerly did, witches would be as numerous now as then, notwithstanding the boasted light and knowledge of the age.

Did you ever know a farmer make much progress of improvement, to be called a good farmer, who delayed sowing and planting till a certain time of the moon? The moon passes round the earth as the sun does every day of the year alike, and is every day and night equally bright and light; but her light side is not seen by us, except when the earth is between her and the sun, or partly so. Why should her influence then, if any, be greater at one stage of her passage than at another? Until men will cease to believe in the influence of the moon and in witches, they will not make good farmers.

The heathen, who knew not God, saw the sun, and that it gave heat and light, caused the rains, and the growth of vegetables; they thought it the great and good spirit who blessed them, &c. They also reverenced the moon, as she illumined the night; and when they had been instructed by the revelation of Christianity, the force of education was so strong, they could not forget the moon, as the cause of their good things. The glorious sun, without which the moon cannot be seen, gets no share of their praise for warming the earth, and bringing forth the crops, but all is bestowed on the moon, simply because it is all mystery. Eh, every thing which loses the mystery, loses its value, with the ignorant. The moon, like a looking glass, only reflects the light she borrows from the sun; and if she has any influence it must be the light reflected only, for she affords not a particle of heat that can be measured.

Would it not be well for you to advise the almanac makers, or those who print them, to omit the figure of the man in the moon, with the signs, &c. in the second page of the almanac? It is a mere pagan practice, of no value, invented to excite wonder and mystery, and entirely devoid of truth. Most respectfully.
DAVID TOMLINSON.

N. B. I have again to admonish the printer of the Cultivator with a fault, in the Recipe I sent for curing pork hams.

It reads, "*rub with fine salt.*" We never rub salt on any hams or beef which are to be put in pickle. If hams were rubbed with fine salt, and left in a warm place two or three days before put into pickle, they would be salted enough in fifteen or twenty days at most. Let "*rub with fine salt*" be dashed out with ink by each holder of the Cultivator.

A reader of the Cultivator has asked what must be the size of the bags for the hams! We answer, that we dare not incumber the Cultivator with useless remarks—That if a dish of suppaun and milk, with a spoon in it, were placed before a man, he should not ask how he should eat it! My hooks are formed like S—The bags may be put in strong pickle, and then dried to make them more tight if desired. Is not quackgrass a corruption? I call it quickgrass, for it is always alive and quick, unless killed by drying it.

Canal Policy.

Schenectady, January 23, 1839.

Dear friend—When the Erie canal was in making, on the flats in Schenectady, I asked the engineers what objection they had to the Mohawk river—that it was a natural canal, much better and safer than any canal made by art—that the bottom would not fall out, as it and the banks of the one they were making would.

All the answer I received was, that they could not make a towing path! I replied, that half the expense of the tow path they were making, would form one on the banks of the river—but that none would be needed, as the broad sheet of water would allow steam-boats to pass and tow the frieght boats of much larger size, and cheaper than horse boats.

But, the answer of the engineer of the Duke of Bridgewater, when catechised by the committee of the Parliament, appointed to learn the feasibility of the Duke's canal, whether it would be proper for the government to loan him aid to finish it—the question was, what are rivers made for? The pert answer was, *to feed canals, sir.* The answer was well in that place, and when canals are made at right angles to rivers; but to make an artificial canal on the banks of a natural one, the river, for the distance of a hundred miles, was a novelty, and in my opinion, a folly.

I told the engineers, that before ten years should pass the business on the canal would so multiply, as to show its want of capacity to meet the great increase of the country—that the time would soon arrive, when every gallon of water in the Mohawk would be wanted for navigation. I grant that my prophesy was not in exact accordance with events—but, the fact, that the canal was discovered to be of too small capacity for convenience, within the ten years, proved to be correct, although the resort to the natural canal, the river, has not been considered by the engineers and commissioners.

Although it is a noble act in man, to acknowledge errors when discovered, and retract, yet our worthy engineers and commissioners are either slow of discovery, or too proud to acknowledge the error.

When I stated to Judge Wright, the objections to digging up the flats, instead of putting locks in the river, he acknowledged the force of the arguments, and said, *we are merely executing the orders of the commissioners, and are not allowed to exercise our own best judgment.* He said, *the commissioners were appointed to make contracts and oversee the execution, and their pride leads them to become directors of the engineers.*

The legislature placed such unbounded confidence in the canal commissioners, simply because the Erie canal has proved to be a successful project, which every one knew as well, would be the fact, that a canal must be the great desideratum for the internal improvements; therefore, as if the discovery had been the result of their gigantic minds, have given implicit confidence to all their projects of improvement and enlargement of the canal.

After spending fifteen millions of dollars in enlarging the Erie canal, by disturbing the farms and villages, &c. with high and inconvenient bridges over farms and highways, it will soon be seen, that the great error must be corrected by abandoning it, and taking the river, (much safer against breaches) and lakes to make a ship canal.

This cannot be seen now, in looking up the stream: but when the ship canal shall be made around the Niagara falls, and the ships advance down to Oswego, that will open the eyes of the judicious, to see the folly of enlarging the Erie canal from the Hudson to Oswego. From Syracuse to Buffalo, the Erie canal is of sufficient size for internal improvement for many years. But, when ships from the far west reach Oswego, they'll say we must go to New-York and the Ocean, or follow the rival canal now making in the St. Lawrence from Kingston to Montreal for ships, and they will then throw away the enlarged Erie, on the banks of the beautiful Mohawk, and adopt the natural canal, the river. It will not cost half the sum to make the ship canal from Rome to the Hudson, that it will to effect the present project of enlarging the Erie canal, by purchasing the expensive property of individuals, &c. The facility of steam, the enlarged boats and ships, in the enlarged and broad sheet of water of the river, will reduce the freight to one-eighth, as well as save half the time, which are two enormous items.

The surplus and waste waters at the dams in the river, will be worth more than the cost of erecting the dams. The dams and locks may be more frequent, and of less depth, than in the Erie canal.

The locks for descending in the right bank, and for ascending in the left bank of the river, to be made out of the way of the current and ice, would be perfectly safe, and afford more expedition. Rolling dams would allow ice and surplus water to flow over with safety, and the whole valley of the superb and picturesque Mohawk, by means of the surplus water powers, for hydraulic use at the dams, would be converted into one continuous village, from the majestic Hudson to the elegant city of Oswego. My remarks, when the Erie canal was in making, had no force, as I was a humble citizen, and not clothed with the wonderful mystery of *engineer.* But, I venture to prophesy once more, that all the canal will be abandoned for the river, from the Hudson to Oswego, by the next generation, when a new class of men come into charge of the canal, who can see, and dare condemn the errors of those who acted before them, without wounding their own pride.

I address you, sir, on this important subject, because the sphere in which you move, has given to your opinions great celebrity in public improvements. If your mind should accord with mine on this subject, it is not too late to effect the alteration in the improvement of the canal. And, I beg you to give some heed to it, before more of the funds of the state are wasted in an error which the next generation must and will correct, after the great waste of millions. With great respect and esteem,
D. TOMLINSON.

South-Down Sheep.

St. Andrews, New Brunswick, via
Robbinston, Me. 14th January, 1839.

Sir—Being a subscriber to your useful and widely circulated paper the "Cultivator," I take the liberty of addressing you, as you appear from your publication to take so lively an interest in the welfare of your agricultural friends.

During a short visit that I made last summer to the state of Pennsylvania, I was much pleased to find a desire to improve the breed of sheep, by importing South Downs into that state, but the great obstacle that offered itself to the flock-masters there, was the difficulty of obtaining good bred sheep from England, as they corresponded with no person who had an opportunity of procuring them, from some of the first flock-masters in England, where *only* they are to be found. I am aware that many sheep said to be South Downs, have lately been imported into the United States; but I very much doubt if they are of that breed; however, I can only speak with certainty of those that have been pointed out to me as such, which were decidedly merely a cross with the Downs, some with the Dishley, or New-Leicester breed, and others with a sheep known in England as the Romney Marsh sheep; which although they fatten early, and kindly, are only calculated for a rich marsh or pasture grounds.

To obviate the before mentioned difficulty I have offered to procure some ram lambs next fall, for any of the gentlemen in Pennsylvania who may wish a cross with the long established, and much admired stock of my late father, Mr. Ellman, late of Glynde farm in the county of Sussex, in England, which are now in the possession of my brothers, who still defy all Europe to produce sheep equal to them. Should any of your neighbors be desirous of trying a cross with this valuable breed, I shall be happy to facilitate their views, and I will engage to import from the above mentioned flock, at $125 each, to be delivered here, a few ram lambs fully equal in blood to the rams now letting on my brothers farms, at fifty guineas each for the season. The purchasers to pay me all reasonable expenses that I may be at for the keep of the lambs after their arrival here. From hence they can be conveniently shipped on board the Eastport packets direct to New-York, or should any one prefer importing them at their own expense, by making arrangements with me for the payment of the sheep, they shall be deliverd on board either in London or Portsmouth, at $102 each, or £20 sterling, if paid for in London at the time of shipment. Sheep at a more advanced age would of course cost more, and any application to me post paid shall receive my early attention.

I recommended the flock-masters whom I met with last summer to try the South Down sheep, remarking on the good qualities they possess; which it would be useless to repeat, as I observed in your number for November 1836, a hasty description of these sheep, which I am satisfied was taken from a treatise on this breed, written by my late father, who it is well known brought the South Down sheep to their present high state of perfection. If the object of the farmer is length of wool, without regard to fineness of pile, or the quality of the mutton, I would not recommend the South Downs, but where both are an object, they are decidedly to be preferred. It must also be recollected that the cross with the long woolled sheep will not bear hard keeping, they are only adapted for good lands; while the cross with the South Downs will stand any hardship, as no other sheep in England are capable of enduring so much exposure, or are so highly prized: and no sheep show a disposition to fatten so early. If I were to enter at large into the good qualities of these sheep, I should trespass too long upon your time, suffice it at present to say, that I challenge all Europe to produce so much weight of mutton from another breed, as I can produce upon the same keep from the pure South Downs, and yet of such superior flavor: for I know from experience, that no sheep in Europe will live on such short keep, nor can any exceed them in symmetry; and it may also be remarked, that the fleece of the South Down sheep, (that of the ram weighing eight pounds,) has within these few years so much improved in quality, that a great part has been considered fit for the manufacture of superfine cloths.

My brothers have lately exported rams to foreign parts, and a great many to Scotland, by which a cross has been gained that has nearly driven the native breed out of the country.

I must in conclusion observe, that as I hold a situation under government, and have no lands at my disposal, I am unwilling to import these sheep, unless I see a certainty of disposing of them, and I can without hesitation warrant those to be of the purest blood.

If you consider these remarks worthy of attention, I will thank you to give them a place in your valuable columns. I am, sir, your very obedient servant,

WM. ELLMAN.

J. Buel, Esq.

Remarks.—We make no pretensions to be a judge of sheep, but we do profess to have an opinion of *mutton*. We have tried the South Down mutton several times during the past year; and we would cheerfully pay one cent a pound more for it than for any other sheep's meat we ever ate. The wool of the South Down bears a higher price in the English wool market than that of any other native breed of sheep.—*Cond. Cult.*

Ruta Baga.

Easton, Pa. January 8th, 1839.

J. Buel, Esq.—Dear Sir—Last season I have raised about one and a half acres of ruta bagas, yielding a little over 700 bushels. I am well pleased with the crop, as respects the quantity, considering the very dry and unfavorable season for roots; they are of great benefit to my cows, producing much richer milk and cream than any thing else I have ever fed them during the winter season, the milk being entirely free from any taste of the turnips, giving my cows a little salt every day. But with all these advantages, I have been much discouraged in the raising of this crop, it having been an immensely troublesome and expensive one to me; they were sown on ridges, in drills, with Merchant's drill-barrow, and owing to the very dry weather, came up very thin, slow, and delicate and were immediately attacked by millions of insects (turnip fleas,) which I tried to stop by sowing all the drills with ashes and lime slaked in urine, but succeeded only partly, and was obliged to water the whole of them with urine from the cistern attached to my stables, which cleared them effectually from all insects. But during these operations the plants of course grew but very little and the weeds entirely overpowered them; (the ground being very rich) then after the horse hoeing, commenced a very slow and tedious hand hoeing, the plants in some places being hardly perceptible amongst the rank and thrifty weeds. A week or two afterwards we had to repeat the same tedious operation, and only after that, and after a few refreshing showers they took a start and commenced growing; when after one more horse hoeing there was nothing more done to them. Now my object is to ask Mr. Buel's advice as to the practicability of a plan which I think of adopting hereafter, and by which it appears to me that in the raising of the valuable roots, the above described, expensive, laborious, uncertain, and I think, general mode of culture, would in a great measure be overcome. It is this: I thought of sowing my seed eight days earlier in a well prepared seed bed, where all the plants for one or two acres would be in a very small plat of ground, and where with little trouble they can be watered and protected from the flea. A few days before I commence transplanting them, I would prepare my field for receiving the plants which I then think would be too strong to be injured by insects or to be outgrown by weeds. (I judge from the few I transplanted last summer, from where they stood too thick in drills, and which at that time were very large and strong, and which all grew and turned out as fine turnips as any in the field, and besides, they were more smooth and had not so many roots as those not transplanted.) First I should commence removing the largest plants from my seed bed, and prepare and plant part of my field according to the number of plants that would be fit; by these means thinning them out and giving the smaller ones air and room to come on, for I think it of much importance to have all the plants stout and strong before they are removed, in which case the stems of the leaves will remain green and erect, and they will take a start immediately, and will then of course be out of the way of weeds and insects. Another advantage I see in this mode, is that the plants will all be placed at regular distances and exactly as I want them; which cannot be the case if they are not transplanted, for some of them will be so placed that, if in thinning them out you remove the one, there will be too much space between the remaining and the next one, and if you remove neither, they will stand too close. I have often heard ruta bagas much praised as a vegetable for the table, but cannot make use of any of mine; we have tried them frequently and could never boil them soft; they would after three to four hours boiling still be hard; or are there different kinds, and mine perhaps not of a good kind for the table?

I hope Mr. Buel will excuse this long letter, about a matter in which I may be entirely wrong, and in reference to which any advice from him would be thankfully received. I have never seen the above manner of raising ruta bagas recommended, and have therefore thought best to ask advice, before I attempted it, of a person in whose extensive knowledge in all agricultural matters I have the greatest regard and confidence. Very respectfully yours,

FREDK. SEITZ.

N. B. I consider the trouble of transplanting the ruta bagas nothing to be compared to the advantages arising from doing it.

Remarks.—Our correspondent suggests the same mode of avoiding the turnip fly, and of obtaining a large crop, that Cobbett employed while farming on Long Island, viz. *transplanting into fresh ploughed ground*—and which he strenuously recommended to others. He obtained in this way, thirty-three tons of roots to an acre, and the transplanting of an acre, occupied him and one hand the morning and evening of three days, the middle of the day (August) having been too warm to work. The great difficulty is to get hands who can use the dibble with facility, and use it well. A smart man will transplant nearly one thousand in an hour, the plants being furnished to his hand by a boy. We have had ruta baga that would not readily boil soft; and we consider such of inferior kind, or planted too early, which is apt to render them ligneous or woody.—*Conductor.*

Culture and profits of Melons.

Narrows, L. I. January 18th, 1839.

Mr. Buel—I will now endeavor to describe the manner in which we cultivate musk melons, and also state the produce and amount of sales from my crops of the preceding four years.

The kind which we at present cultivate, and with which the New-York market is principally supplied, is known among us by the name of Skillman melons. They average about six inches in diameter, are nearly round, have a rough skin, and their flesh is of a green colour. This is the sixth variety which has been in vogue during my recollection, and the finest of them all. The seed from which all these varieties originated, I believe to have been imported from the coasts of the Mediterranean. They soon degenerate unless care is taken in the selection of the seed. We prefer for melons a rich sandy soil, and on this they flourish better than on any other, and are not so liable to speck in rainy weather. When planted on a red clover sod I have seldom failed having a good crop, but when this is not to be had, we prefer preparing the ground by sowing with rye in August or September of the preceding year, as described in my former communication on the cultivation of cucumbers: the ground is also prepared in a similar manner in the spring, except that the hills are furrowed five feet apart, and the same kind and quantity of manure made use of.

We generally commence planting about a week later than we do cucumbers, but occasionally at the same time, dropping from twenty to thirty seeds into a hill, and covering them about an inch deep with fine soil. Eight or ten days after putting in the first seed we commence planting over, which we seldom perform the second time unless by examination we find the first seed about to fail. The seed of melons is not as liable to rot as that of cucumbers, but long storms are very apt to destroy the young plants, and they will even produce great injury when the plants have vined from off the hills. In 1837, a succession of wet weather caused the ends of the principal part of the melon vines in our vicinity to die as late as the 8th of July, but mine fortunately did not suffer as much as those of my neighbors. We cultivate the plants in the same manner as cucumbers, except that in hoeing, it is generally necessary to remove a small portion of the soil from between them, in consequence of their being too short to admit of the young weeds being covered without injury to the plants. We gradually thin them down to four in a hill, standing from five to six inches apart. The plants are liable to the depredations of the same species of insects which prey upon cucumbers, and they are destroyed in the same manner.

Melon vines are in bearing from five to six weeks; whenever a drought occurs, this period is much less, for that of 1838 finished mine in four weeks. They often bear a second crop which answers for pickling, but I have known this crop to come to perfection.

When the fruit is ripe, it requires to be gathered every day, otherwise there would be large quantities lost in consequence of becoming too ripe and soft. When ripe they have a yellowish colour, but such as are cracked around the stem and come off easily from the vines, we always gather, for they will be fit for eating by the next day, when sold in the markets.

To ensure good crops, melons should not be planted two years in succession on the same ground; they require a rotation. Marshall, an English writer, recommends the carrying of cucumber and melon seeds a week or two in the breeches pockets previous to planting, to dry away some of the more watery particles: were we believers of this doctrine, it would be a difficult matter and require large pockets, or a regiment of small ones to carry it into practice, since some of us, to secure our crops, plant from three to four bushels of seed in a season.

The following is the number of hills planted, produce (large quantities of unsaleable ones fed to the hogs excepted) and amount of sales for the preceding four years, viz.

Year.	Hills planted.	Bushels sold.	Amount received.
1835,	6,664	1,133	$939 10
1836,	7,850	561	590 57
1837,	8,011	990	913 56
1838,	7,590	823	713 96

Yours, TUNIS G. BERGEN.

Great product of Sugar Beets.

Albany, January 1838.

Mr. Buel—Sir—The following account of a most extraordinary yield of the sugar beet, was communicated to me, in a letter, from Mr. Samuel Guthrie of Sacket's Harbor. I regret he omitted to give his mode of culture, nature of the soil, &c. &c. as we could then probably profit by his experience.

I cultivated a small patch last season, of sugar beets and carrots, but my crop did not begin to compare with his—still I am so well convinced and satisfied with their value for feeding stock, that I have determined to try them again, the coming season, should my life be spared.

My cows, calves and hogs, prefered them to the ruta baga, while my sheep prefered the latter.

I feed my horses carrots, one meal per day, and think them equal to oats—bushel for bushel—it not only keeps them loose, but gives them fine glossy coats.

CALEB N. BEMENT.

THE EXTRACT.

"I observe in the Cultivator," says Mr. Guthrie, "that you had great success, last winter, in wintering hogs on ruta bagas. You have not probably given a trial to the French sugar beet. From some experiments I am induced to think that the French sugar beets will prove to be the best and most economical food for the hog, to be found among the root tribe. In the same enclosure, last summer, I raised, in the ratio to the amount of ruta baga of about 500 bushels, of carrots 937, and of French sugar beet the very large quantity of 2176 bushels to the acre. The soil and advantages of culture the same in each. The ruta baga was greatly injured by insects, *while the beet was without an enemy*. The cost of the sugar beets, which, by the bye, were almost as white and smooth as hens eggs, scarcely exceeded one cent per bushel. I washed and sliced a quantity of ruta baga, carrots and beets, and fed all at once to my hogs, on a few occasions, and was induced to believe that the hogs gave the preference to the sugar beet. I am zealously preparing for the purpose, and intend to feed a few thousand bushels of French sugar beets another winter, at all times thoroughly steamed, with a slight admixture of bran, shorts, or ground screenings, and I have no doubt but I will winter a swarm of hogs in this way for a less expense than has ever been heretofore done."

Hints to those who raise great Crops.

New-York, January 18, 1839.

Mr. Buel—Dear Sir—I take my pen with reluctance, inasmuch as I fear some unpleasant feelings may arise from what I have to say; but as I have no object in view but to vindicate the propriety of fairness and truth, I hope none will be offended. I have all the volumes of the Cultivator, and the pleasure they have afforded me, has induced me to obtain several subscribers to the work. In so doing, I used no other argument than this, viz. that it contained more matter of fact than any other agricultural periodical I had ever met with, and I am sorry to say, that some recent communications are calculated to create wrong impressions. While reading the last number, my attention was drawn to a close examination of the several statements in relation to the corn and ruta baga crops, each of which foots up a large amount of profit, and that is the only point I shall now consider. Statements made up in this manner, are calculated to do injury, not to the experienced farmer, but to the new beginners and persons unacquainted with agricultural pursuits. If you examine the statement of Mr Osburn, I think you will sustain me in this position. He states that he planted and cultivated three acres of corn, and that the cost of so doing was $61.80, and that the best acre produced a nett profit $87.71; had the other two acres produced as well, the whole profit would have been $263.13; i. e. if the statement is a fair one. I think it an unfair one, and believe many others will form the same opinion. It is difficult for us city people, who do little with corn but cook and eat it, to see how a farmer can buy and fence land and then furnish 50 loads of manure to the acre; and think the expense too trifling to occupy a place in the accounts of his farming operations. This is what I complain of, telling the truth, but not all of it, leaving the uninformed to guess at what is omitted in the debit side of the account, or pass it as unimportant, whilst on the other side, we find every thing set down with the most scrupulous accuracy, even to the stalks and pumpkins, and yet the land, manure, replanting, shelling, gathering pumpkins and stalks are forgotten. Now I can believe that 118 bushels of corn were raised on the acre, but must protest against the claim to so great an amount of the proceeds as profit—profit, you know is the pith of every thing, in these days, and if the farmers take the Frenchman's plan of calling the amount of sales nett profit, I fear the stock will fail. But let us look a little farther, and see how the profit is made out. First, one man, two boys, one horse, and two cattle, worked at the manure ten days for $10. Only look at that to begin with. Why, sir, you or I would have asked that amount for the board and keeping of the cattle during that time, and thought it little enough too. Then look at the hoeing; thirty-four days work of men and boys, horse and cultivator all for $13.87. Who could not realize large profits from any business with labor at that price. I do not mean to infer that more wages was given than was stated, but is it fair to publish it to prove the profit of raising corn? Look at it again; divide $61.80 by the number of days spent by men, boys and beasts in cultivating this crop, and you will find that the amount of each day's work would purchase about 23lbs. of this same corn. Now the beasts might live upon this quantity of food, but the men and boys could not, and buy their lindsey woolsey too. In choosing the statement of Mr. Joseph S. Osburn as the subject of these remarks, I entirely disclaim every thing of an invidious character. Many of the remarks would apply equally well to other statements found in the Cultivator, and I shall leave it to your correspondents to apply them where they will suit best, and respectfully ask them to continue giving us the result of their labor and experiments—give us the truth —the whole truth—sound conclusions, drawn from the new, enlightening and profit working doctrines taught and practised by the ablest agriculturists of our country; then, only, will we rightly understand and profit by each other's experience. The day is not very far distant, when one man and one acre will produce more than two men and two acres now do, taking the state together. All that is necessary to bring about a result so desirable, is to encourage and circulate sound and well conducted agricultural papers, particularly those which give as much practice as theory. Then those who will may learn farming as they learned their multiplication tables—learn to connect facts as they connect figures, and learn too the relation they bear to each other.

I have continued this scribbling to an unreasonable length, but must urge one thing which is worth more than all the rest. Let every farmer and mechanic learn the science of his business—or in other words, the connection of parts, and how each and every one is related to the other, that he may be enabled to place each part in the most advantageous position. When the mind and body are engaged in the same business, the hands forget to tire. Study is therefore no hindrance. If any of the above is worth publishing you are at liberty to select and use it as you think proper. Respectfully yours, &c.

JOHN M. DODD.

☞ There is much truth in the remarks of our correspondent. We could wish that these details were given with more accuracy; but we do not feel at liberty to correct them in this respect. Our object in offering the premium, was to increase the average profit of the corn crop, by concentrating labor, and inducing a more enlightened mode of culture. We consider this object has been promoted in the culture of the crops which have been presented for premium—that the soil has been made to yield a greater product, without a corresponding increase of expense. We looked simply to the fact, that while the expense of culture was no greater than is ordinary, or should be, the crops were three-fold greater than common. Our correspondent is not aware of the fact, that manure has not yet hardly a nominal value in the west, and that many farmers are glad to have it removed without price. These corn crops afford a demonstration of its intrinsic value—and hence, too, results in a benefit to the public.—*Cond.*

National Agricultural School.

Washington City, January 22, 1839.

Jesse Buel, Esq.—Sir—I learned with great pleasure, from your letter of the first inst: that you approve of my proposition, of having an agricultural school erected from portion of the Smithsonian legacy.

The most effective way of carrying this object, would be by petition to Congress from the agricultural societies, from several parts of the Union, and principally, as you mentioned to me, in discussing it in the agricultural journals.

Probably you have received my memorial on the manufacture of beet sugar; I do myself the honor of presenting you that of the proposed agricultural institute.

I take the liberty of sending you two packets, which I request to deliver to the addressed assemblies of the coming month.

Should I go to Europe this coming spring, I shall take a tour of the continent, to investigate not only the new improvements in the manufacture of beet sugar, but also agriculture in general. Should you or the assemblies honor me with orders, I should feel happy to at tend to them. Very respectfully,

CHARLES LEWIS FLEISCHMANN.

Queries.

Morristown, Feb. 7, 1839.

Jesse Buel, Esq.—Dear Sir—Will you be good enough to give to a subscriber information upon the following points, 1st. If a farmer go to the expense of sending to Albany for a pair of Bement's Berkshire pigs, what course or rules of breeding must he adopt to keep his stock pure, or in other words, how shall he prevent the degenerating effects of breeding "in-and in?" 2nd. (As extracted from the *Farmers' Cabinet.*) "What is the best method known among our builders and mechanics of protecting northeast brick walls, and generally of keeping stone and brick houses dry?" 3rd. Has the French *Asphaltum*, which is now used in France and England, for roofs, side-walks, &c. been applied in our country to protect northeast brick walls, from our heavy storms?—if so, where, what is the expense per square yard, and with what success?

If you have not turned your attention sufficiently to the last question, to give the requisite information, will some one of your numerous subscribers answer the same. For although it may not be strictly an agricultural question, yet it relates to the protection and preservation of brick walls, in which many of your readers are equally interested with the SUBSCRIBER.

REMARKS.

1. The degenerating effects of breeding in-and-in, can only be avoided by crossing with other families or other breeds.

2. For protecting the northern walls of houses from the weather, or of keeping stone or brick houses dry, the only expedients we have known to be adopted, are to cover the exterior with cement, to saturate it with oil paint, or to cover it with a coat of white wash. Mr. Coke uses the latter as a preservative to wood as well as walls. For this purpose the lime is used fresh from the kiln, and clean sharp sand, and mixed with hot water, and laid on hot. Our brick walls have been covered with a lime-wash, we believe with the addition of a little salt. The wash appears nearly as durable as paint; and although we consider it some protection, it does not prevent the interior of the walls becoming damp in the spring and during long spells of damp weather.

3. Asphaltum has not been applied in America, that we have learnt, to the purposes noted by our correspondent. Asphaltum is a species of mineral tar, composed according to the analysis of Klaproth, of 32 parts of bituminous oil, 30 of charcoal, and 20.50 of water, silex, alumine, lime, and the oxides of iron and manganese. It abounds in the West Indies, and particularly in the island of Trinidad. It becomes solid on exposure to the atmosphere, and burns readily. We are not acquainted with the foreign modes of preparing it for pavements and roofs. We invite some one capable to supply our deficiencies in this matter.—*Cond.*

Mode of destroying Pea Bugs, &c.

North Mansfield, Feb. 14th, 1839.

J. Buel—Dear Sir—For about ten years, I have directed my attention specially to the cultivation of select kinds of the garden pea, *for seed*. By care, and the selection of the purest and ripest seed from year to year, the quality of the seed became greatly improved; and practice enabled me to ascertain the most successful mode of cultivation. My garden contains one acre; upon one fourth part of this, I have raised in different years from four to seven bushels of pure seed, in value from five to six dollars per bushel.

I have frequently seen it stated, that *worm eaten* peas were not materially injured for seed; but I have proved by experiment, that they are of little value. Such of them as vegetate are of feeble growth, and a very considerable proportion will not germinate at all.

As soon as my seed is *well ripened,* I put it in large jugs, of any convenient size, well corked and sealed. The egg of the insect, within the pea, is at this time in such a state as not to injure the seed, and not being able to change its form, or to grow *without air*, the seed remains until needed for use, entirely without injury. Seed of this kind is of more than double value, compared with that ordinarily sold; and by repeatedly sowing such seed, *the ravages of the pea bug*, I suppose may be in a great measure prevented. Families should be careful to reserve their *earliest and best seed,* and as soon as it is perfectly mature, seal it in bottles. If the seed is not *dead ripe,* the matchless and some other delicate varieties, will to an extent fail of coming up; and any considerable delay in bottling will allow the bug time to commence his work.

My principal object in writing to you, is to name a disease, which in this region, for a few years past, has seriously affected the culture of the garden pea: how far the field pea has suffered from the same cause, I am unable to state; though there is evidence, in some cases, of a new form of blight.

About four years ago, I observed that the plants in a few distinct places in my beds, began, after two or three weeks growth, to appear sickly, and gradually to turn yellow. I examined the roots, but could perceive no evidence of any insect. From that time to this, the disease has extended, till the profit of culture is destroyed. I first heard complaints on this subject in dry gardens, perhaps six or eight years ago, and attributed the evil to the quality of the manure, but am now convinced, that the cause was the same from which the gardens in Connecticut are extensively suffering.

The following facts I have ascertained relative to the disease mentioned.

1. It appears in places widely remote from each other, and in instances in which the seed is obtained from different sources.

2. Dry soils, which ordinarily are best adapted to the cultivation of the early pea, suffer most; and heating manures cannot be used in such soils.

3. The early pea is most subject to the disease; but even the hardy garden marrowfat, is often diminished in its products one half. Many plants prematurely turn yellow and some entirely die.

4. Ground planted with the pea for successive years, bears the most decisive marks of the disease; but change of soil does not entirely remove the evil.

This calamity, if it should extend, will be very serious. It has nearly ruined the profits of my garden, the last four years. I design to apply remedies the ensuing season, and shall employ *salt*, first of all. If you can communicate any facts with reference to the disease, or its remedies, you doubtless will oblige very many.

I will only add, that a disease, *something similar*, has in a few instances affected whole fields of maize, without any appearance of insects at the root, as I have myself observed. A few spots upon the leaves were the first indications of disease, while the plants were from one to two feet in height; and soon the whole field changed its colour to a sickly yellow, and scarcely any product was obtained, though the plants reached about their usual size. A neighbor pointed out this disease in a field of mine, two years ago, and his predictions of the result were more than realized. Truly yours, a constant reader, GULIELMUS CLERICUS.

Advice Asked.

New-Baltimore, Va. Feb. 11, 1839.

Dear Sir—I think the advice which you give in the Cultivator, is generally excellent, but owing to circumstances it does not always meet our cases. Your soil is better than ours, your farms smaller, and your laborers different. I will describe a concern here which actually exists, and ask you to conceive yourself the proprietor, and say what your course would be. Agricola has a farm of 490 acres, about 350 acres of it open, and in cultivation; the soil a mixture of sand and clay, the preponderance rather in favor of the former. The yield from seven barrels to one of corn to the acre, planted at right angles, four feet distance, two stocks in a hill—of wheat, about fifteen to three bushels per acre, when fallowed; on corn land, less; about seventy-five acres of the farm in clover, a small portion of low land, but the greater part is high and rolling; the whole farm under pretty good enclosure, laid off into nine fields. He has a family consisting of himself, wife, and six children, all daughters excepting the two youngest, entirely unable to labor; also nine slaves, of whom, one is a man, another a woman, a lad and two smaller boys, the rest children unable to work. He has a tolerable supply of horses, cattle, hogs, and sheep; and of farming utensils; a year's allowance, and but little money. Hirelings cost from $8 to $10 per month. Now as this is a real case, you will oblige a subscriber by saying how you would proceed, if you were the proprietor. Let your answers come out in the March number, if convenient. Yours most respectfully,

JNO. OGILVIE.

Plaster costs from $5 to $6 a ton—lime too far off to be procured at reasonable cost, and no manure to be obtained, besides what is raised on the farm. J. O.

ANSWER TO THE ABOVE.

Agricola works 350 acres of land, from all appearances materially good, with two grown persons and three lads, besides himself, the whole not exceeding five efficient hands, being about seventy acres to each laborer; and he gets an average product of twenty bushels of corn, and nine of wheat, taking the mean of his numbers, from an acre! In other words, he barely makes out to live upon the product of his 490 acre farm, while many a Yankee not only lives, but lays up money, upon a tenth of these acres. The difference in the two cases arises principally, we suspect, from the capital, the labor and the skill, which are employed on the smaller, and not on the larger farm. And the best way of equaling the Yankee in profits, is to imitate him in practice. We therefore advise Agricola, to concentrate his spare capital, his manures, and his labor, upon fifty acres—forgetting that he has any more, except for the range of his cattle—and to confine his efforts to the improvement of these fifty acres, till he can grow upon each and any of them, sixty bushels or twelve barrels of corn, and at least twenty bushels of wheat. Manure is the first requisite to improvement. Let him save, therefore, every refuse animal and vegetable substance, and apply it economically. Clover may contribute much to fertility, if ploughed under before it has run out, or been eaten down to the ground. The beet and Swedish turnip, besides affording much to the farm stock, return much to the soil in the form of manure. Let him plant no more corn than he can manure well; and sow no wheat till he can grow sixteeen bushels an acre. Let him alternate grain, and grass and roots. In this way, with Yankee industry, in six or seven years, we think the fifty acres will be made to yield him more than 150 acres do now, and with one third of the labor he now bestows, or ought to bestow, upon the latter. Let him keep up the fertility of this fifty acres by the same means that he raises it; and he may then apply his surplus means, the profits of the fifty well cultivated acres, to grapple and bring forward fifty other acres to a like condition.

We commend to the notice of our correspondent the communication of Mr. Garth, of his state, inserted in our last number, and our notice in this sheet, of the excellent practice of Mr. Brewer, of this state—both detailing the means successfully adopted for renovating lands, and rendering them fertile—*Cond.*

A new Wheat.

Galena 24th Jan. 1839-

Jesse Buel—Dear Sir—I send you enclosed some few grains of my many headed Santa Fee wheat—I am yet at a loss to find, whether the kind I have is the winter or spring variety—(they have both in New-Mexico) the berries I send you, were produced from a sowing made on the 20th of May last—they are defective; I have planted some of that grain last fall, as winter wheat. I hope yet that some one may succeed in raising that grain to perfection, as I am convinced of its superiority both in yield and quality, over any other wheat raised in this country. I have had some single straws produce as many as fourteen lateral ears, besides the centre or main ear, the laterals being about one-third of the length of the main ear. I have several valuable varieties of Indian corn or maize; two kinds procured from the Indian tribes that inhabit this section of country, both very early, productive, prone to succoring and producing ears on them, besides other kinds; if you are desirous of obtaining some of those kinds, I will forward them to you *post paid*. I cultivated last summer, for the first time, some of your Buel corn, which I take to be the same as the Dutton—I am satisfied that it is two weeks earlier in this climate, than it is in yours, or in the same latitudes in your state. I prefer other larger kinds of maize which we cultivate in this climate, although not quite as early, ripens well here, and bears larger ears, long seeds and small cobs, and will shell out a struck bushel of grains to three half bushels in the ears, heaped. I forward you also enclosed, a few grains of a kind of white corn, which having a large cob and desirable seed, I transplanted upon the cob of a yellow variety—in this way the corn I got was the production of the two kinds above mentioned, of course a mixture of white and yellow grains, mostly, however, upon the large cob. I however found a few ears that retained the desirable small cobs and a mixed seed; from these I selected carefully all the *perfectly* white grains, planted them apart from other varieties, and raised the beautiful white grains now sent you, without a single yellow grain, and retaining the small cob. This variety, I am confident, will be found early enough for your climate, and preferred from the whiteness of its grain. I am very respectfully, &c. JAMES G. SOULARD.

We believe yellow corn is generally more rich in nutritious matter, and the meal from it more grateful to northern palates, than the meal from white varieties.—*Cond.*

Queries and Answers.

Tuckasaga P. O. Mecklenburgh co. N. C. Feb. 4, 1839.

J. Buel—Sir—Will you or some of your correspondents please to answer the following queries. 1st. What is the best mode of destroying broomsedge or broom grass in meadows? 2nd. What is the best mode of destroying dock in meadows? 3rd. At what time, and how, ought bees to be put into the bee house, to be raised and managed on the housing plan? 4th. How is the horizontal hill side ditch and graduated furrow laid off, at what part of the field or hill side, is the best to commence at, and how many inches descent in the rafter level of twelve feet span is necessary to prevent hill sides from washing? I would like very much to hear the whole process explained, as I understand it is practised pretty extensively in some parts of Virginia. Respectfully yours. [illegible] H. McHEARY, P. M.

ANSWERS BY THE CONDUCTOR.

We leave the first and last part of the fourth query to be answered by some Virginia correspondent, where we believe broomsedge grows, and where the business of preventing and healing gauls is pretty extensively practised; and proceed to answer the other queries.

2. The only effectual mode of extirpating dock in meadows, is to destroy entirely the root and top; and the best mode of doing this is to pull them up, before the grass is mown, which may generally be affected with ease, by seizing the seed stock near the surface, and drawing up the roots. The entire plants should be gathered in piles by boys, and when dry enough, burnt to ashes. The labor is not great.

3. Bees should be put in the bee house the evening after the new swarm has come out—or any other time will answer.

4. If we understand the fourth query, the first part relates to draining on a wet side hill. The ditch or under drain should be laid off just above where the appearance of the surface indicates an excess of water, and dug through the porous or watery stratum, and so far into the subsoil or pan, or till, as to form a channel in the latter for the conveyance of the water; and it should not have so great a descent as to cause the water to wear upon the bottom or sides of the drain. A second and a third drain are often necessary below the first, in consequence of spouts or springs bursting out there.

Prevention of Smut—Lunar influence.

Clinton, N. Y. January 26, 1839.

Mr. Buel—Sir—With your permission, I will briefly state the result of my efforts to prevent smut in wheat. I prepared the seed for one field by washing (not steeping) in a strong brine, following with lime in the usual way, and sowing immediately. The result was an almost perfectly clean crop. For another field, the seed was merely washed in fresh water, and limed as before. As the sowing commenced, it began to rain, and continued until the seed was all harrowed in. At harvest, I found a very smutty crop. I am inclined to account for this by the substitution of fresh water for brine, or putting the seed in during a rain, or by both united. The latter I am now *sure* was a great error; *suspected* so in the time of it, and hope not to commit the like again.

With respect to "lunar influence," I wish to say a word. If it be as great as some suppose, the subject is a very important one. Without having any decided opinion as to its nature or extent, I entertain some doubts whether the facts stated by your Plymouth correspondent, in the Cultivator for December, are the result of "lunar influence." Some years since, hearing the remark that pork killed in the new of the moon would swell in cooking, and noticing that my pork that year did swell finely during that process, I at once referred to the time of butchering, and found it to have been performed at precisely the opposite period. I think the result was similar in another instance. It would seem, at least, that if the common saying is *sometimes* verified, it is not *always* the case. Very respectfully yours, G. BUTLER.

P. S. I will just mention that I made an experiment last spring, with the contents of an old vault or privy, notwithstanding the fears of some, that it would prove the death of vegetation. It was applied to corn ground, in the hill, at the rate of about twelve loads to the acre. Perhaps a less quantity would have done as well, and a compost form I now think the best way of applying it. The result, however, was astonishing, producing a most luxuriant growth, far exceeding that portion of the field prepared with manure from the hog-pen. A heavy and destructive wind about earing time swept over the field, breaking a large number of stalks, of course greatly reducing the crop. G. B.

New Implement—New variety of Corn.

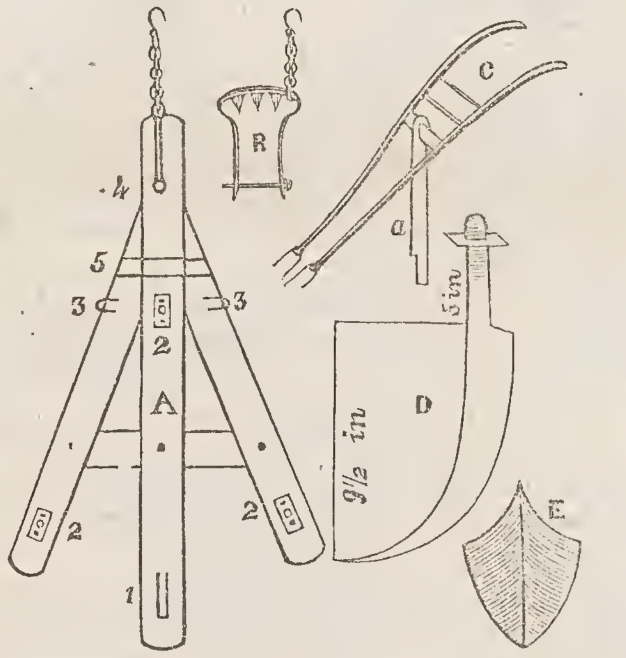
Madison, Ia. January 1, 1839.

J. Buel—Dear Sir—The drag or harrow, here described, is the best implement for the cornfield, market garden and "truckpatch," I have ever seen. It is prefered to and takes the place of the *cultivator*, where both are known, the superiority consisting mainly in the circumstance of its getting deeper into the ground and leaving it in a situation much less likely to *bake*. I obtained a drawing and description from my brother in Maryland for the benefit of this state; a copy is annexed for the benefit of mankind.

Do you eat roasting ears? so called because they are almost always boiled—If you do, plant Tuscarora and sugar corn together in equal quantities, and you will obtain an article superior to any thing you have ever tasted in the shape of corn. I raised a small quantity this year, which was the "town talk." It appears from that which I have saved for seed, that the sugar-corn mixes with the Tuscarora, and not the Tuscarora with the sugar. I will send you a few ears of that mixt corn. Would not the *sugar grains* in these ears, as they are much larger, produce a sugar corn superior to the old? I mean to try it. Yours with much regard,

G. FITZHUGH.

[Fig. No. 3.]



DESERIFTION.

The frame is made of good oak timber, 3 inches broad on top, by $3\frac{1}{2}$ inches deep. The middle piece is 3 feet 2 inches long—the clevis hole seen at 4 is $4\frac{1}{2}$ inches from the end; the front tooth in the same piece is $10\frac{1}{2}$ inches from the end, and seen at 2 in a square long plate with a round hole for the neck of the tooth, to come through; at $2\frac{1}{2}$ inches from the hind end of same piece is a vertical mortise, $2\frac{1}{2}$ inches long and 1 inch broad, for a post to support the handles—the post is made of strong timber $2\frac{1}{2}$ by 3 inches square, and is $19\frac{1}{2}$ inches long—it has a tenon $3\frac{3}{4}$ long by $2\frac{1}{4}$ broad and 1 inch thick, to fit into the mortice at 1—at 11 inches from the shoulder of the post, commences another mortise (in a different direction of the tenon) $2\frac{2}{3}$ inches deep and 1 inch wide, into which is to be fitted a cross to support the handles, tapered and rounded to go into the handles which fit on both sides of the cross, with $\frac{7}{8}$ hole about 2 feet 3 inches from their lower ends, and extend back about the same distance, having a round behind the cross to confine them together, at 1 foot 5 inches from the upper ends, and are 1 foot 6 inches wide at the round. The side pieces are 2 feet 6 inches long, and join the middle piece opposite the clevis hole, and are united to the centre piece by a slat $3\frac{1}{3}$ inches broad at one end, and 3 inches the other, 1 inch thick and 18 inches long, the mortice for it to commence $7\frac{1}{4}$ inches from ends of side pieces. The teeth are placed in these at the distance of $5\frac{1}{2}$ inches from the ends as in the number 2. The teeth are made of best bar iron $1\frac{7}{8}$ by $\frac{7}{8}$ inches—the necks are 5 inches long, and are at the shoulder $1\frac{1}{4}$ inches by $\frac{7}{8}$ square, and are tapered and rounded at the top for a strong screw—in the side pieces they must be placed obliquely that their tracks may be parallel with the middle. They must have strong plates for the bottom, say $\frac{1}{4}$ inch thick, $2\frac{1}{4}$ broad, $4\frac{1}{2}$ long, and well nailed on; the top plates much lighter, and the holes for the teeth in the bottom plates must fit the necks well and of course must be cut into the sides obliquely to give the proper direction as before intimated—the shoulders of the teeth must fit well; with a cold punch, indent the numbers respectively behind the shoulder of each tooth, and on each plate and nut, to distinguish their places.

N. Y. State Agricultural Convention.

Tuesday, February 5, 1839.

The Convention met in the Assembly Chamber at 4 P. M. Judge VAN BERGEN, of Greene county, was called to the chair, and Messrs. Bird, of Erie, and Fry, of Montgomery, were appointed Secretaries.

On motion of Mr. Buel, of Albany, a committee of eight was appointed to nominate officers of the convention. The committee, after consultation, reported the following:

DERICK SIBLEY, of Monroe, *President.*
John Crary, of Washington,
Corn's Bergen, of Kings, } *Vice-Presidents.*
J. L. Voorhees, of Onondaga,
Nathan Clark, of Washington,
W. A. Bird, of Erie,
Richard Keese, of Essex, } *Secretaries.*
Z. Barton Stout, of Ontario,

The counties were called alphabetically, and the gentlemen present from each were desired to hand in their names to the Secretaries. The number of gentlemen who thus identified themselves with the Convention, amounted to between one hundred and eighty and two hundred.

Mr. Buel read a letter from C. L. Fleischmann, a graduate of the Agricultural School of Bavaria, transmitting copies of two memorials which he had presented to Congress, one for the establishment of a National Agricultural School, from a part of the Smithson legacy; and the other, giving the history of the sugar beet business down to the present time, and detailing the recent improvements in the manufacture. From the latter document, which was read in Convention, it appears, that by a summary and cheap process of drying, the beet root may be preserved so as to be manufactured at any season; that the process of drying so lessens its volume and weight, that it may be transported at one-fourth of the former expense; that the beet is now made to yield ten per cent of sugar, and that the process of manufacture has been so simplified and cheapened, that refined sugar, equal to our loaf, can be sold for seven and a half cents per pound.

The thanks of the Convention were voted to Mr. Fleischmann for his communication.

On motion of L. F. Allen, a committee, consisting of Messrs. Buel of Albany, Walsh of Rensselaer, Ogden of Chemung, Bergen of Kings, Sacket of Seneca, Patterson of Livingston, Tiffany of Montgomery, and Potter of Dutchess, was appointed to report the business to be presented to the Convention for its consideration.

Mr. L. F. Allen offered a resolution in favor of a memorial to the legislature, requiring assessors in the several towns and cities to ascertain the annual quantity of agricultural products, and the value of our domestic manufactures.

The resolution was debated by Messrs. Allen, Petrie of Herkimer, Chandler of New-York, Clark of Washington, Beardsley of Otsego, and Strong of Monroe; and before the question was taken, the Convention adjourned to 7 o'clock.

7 o'clock, P. M.

Mr. Allen offered the following, as a substitute for the resolution which he had before moved in the Convention; and after some debate, it was adopted.

Resolved, That this Convention respectfully request the Legislature of this State to pass an act making it the duty of the assessors in each city and town in this State annually to ascertain the whole amount of the produce of said city and town, including agricultural, mechanical and manufactures of every description, designating each separately, in proper tables, so that the specific produce of said city or town may be seen by the items respectively; and in order to obtain particularity and uniformity, the Secretary of State be required to make blank tables or forms, such as he may deem proper and necessary, to ascertain the entire produce of the State of every description; that such blanks may be furnished to the clerks of each city and town in order that they may be distributed to such officers whose duty it is to obtain such information; that said officer be required to make due return thereof in such manner as shall be designated by the Legislature, and that the Secretary of State may make due report of all such information so acquired, to the Legislature annually, in the month of January.

Mr. Buel, from the committee appointed to prepare business for the Convention, reported, in part, the following resolutions:—

1. *Resolved*, That in the opinion of this Convention, the culture of silk is an object well worthy of legislative encouragement by the offering of bounties for a limited number of years for its production.

2. *Resolved*, That this Convention regard the culture of the sugar beet, with a view to the production of sugar, as a branch of agriculture, which may be prosecuted to the very great advancement of the prosperity of the State, and recommend it as well entitled to legislative encouragement by the offer of liberal bounties.

3. *Resolved*, That this Convention regard it of very great importance that a brief treatise, containing plain directions for the growing of the mulberry and the management of silk worms, should be prepared and distributed to each of the common schools in this State.

4. *Resolved*, That the introduction into all the common schools of this State, of a short practical treatise containing plain, simple directions for growing the sugar beet, and extracting the sugar therefrom, according to the latest and best process, would in the opinion of this Con-

vention greatly contribute to the general introduction of this new branch of national industry, which promises so greatly to increase the prosperity and promote the welfare of the people of this State.

5. *Resolved,* That this Convention cordially concur in the recommendation of his excellency the Governor, in his annual message to the present Legislature, that publications upon Agriculture, Horticulture and Rural Economy, ought to constitute a part of every common school library.

6. *Resolved,* That this Convention respectfully and earnestly recommend, that the Legislature make provisions for procuring and distributing the above named publications, and that the expense thereof be defrayed out of the fund appropriated for common school libraries.

After some debate, in which several gentlemen took part, the three first resolutions were adopted, when the Convention adjourned till 4 P. M. on Wednesday.

Wednesday, Feb. 6.

The three last resolutions submitted yesterday, by Mr. Buel, were taken up, discussed, and adopted.

Mr. Buel, from the committee appointed to propose business for the Convention, reported the following resolutions.

7. *Resolved,* That as agriculture is the great business of the state—whether we regard the numbers it employs, the magnitude of its products, or the wealth and comfort which it confers—so it ought, at all times, to receive the peculiar and fostering care of the representatives of the people.

8. *Resolved,* That in the opinion of this Convention, agriculture has not hitherto received, from the people's representatives, that stimulus to improvement which sound policy would justify, and which equal justice and the best interests of the state demand.

9. *Resolved,* That the products of our soil may be vastly increased, our revenue augmented, the wealth and comfort of every class of our citizens promoted, and the character and prospects of our state elevated—by a judicious and liberal appropriation of public moneys, to enlighten, to stimulate and to reward, that numerous portion of our fellow-citizens who are employed in the business of agriculture.

10. *Resolved,* That an annual appropriation of twenty-five thousand dollars of public, moneys ought to be made, for a term of years, to encourage improvements in agriculture; and that in the opinion of this Convention it will return an annual interest to the treasury, and compound interest to the state.

11. *Resolved,* That the general principles of the bill, to encourage agriculture, reported at the last session of the legislature, by the committee on agriculture, meet the views of this Convention, and that we respectfully request that those principles be adopted by the Legislature now in session.

12. *Resolved,* That the American Institute richly deserves the fostering care and liberal patronage of the Legislature, as an institution which has already done much good to the state, and which is eminently calculated to promote great and rapid improvement in the mechanic and manufacturing arts, and materially to aid in the improvement of agriculture.

13. *Resolved,* That the offer of liberal rewards for the discovery of preventives to the depredations of the grain worm, weevil, Hessian fly, and other insect enemies, which prey upon and seriously injure our farm crops, while it might effect much good, by leading to useful discoveries, could not result in loss to the state, inasmuch as the benefits of the discovery, if any should be made deserving of the rewards, would greatly overbalance their amount.

14. *Resolved,* That the establishment of common school libraries will form an important era in our history, and is eminently calculated to advance us in the march of useful knowledge, to multiply our domestic and social comforts, and to elevate our character—provided that judicious selections of books are made for such libraries—adapted to the capacities and understandings of those whom they are designed to benefit, to the wants and improvement of the various branches of productive industry, and to the promotion of industrious and moral habits in the rising generation;—and that in this view of the subject, the appointment of a competent board to prepare, or cause to be prepared, a selection of books for common school libraries, by the Legislature, at least so far as the public moneys are to be applied to this object, is called for by the highest considerations of public usefulness.

After some discussion, the above resolutions were severally adopted, except the 13th; for which Mr. Clark, of Washington, offered the following substitute, which was adopted in its stead.

Whereas, the growing of wheat is a business of great importance, not only to the agricultural but also to the mercantile, manufacturing, commercial and financial interests of this state:—*And whereas,* the eastern and northern portions of the state have, for some years past, been visited by the ravages of insects which have destroyed the crops therein, and reduced the farming interests thereof to dependence on their western neighbors for their supplies of flour:—*And whereas,* this Convention view with alarm, the rapid spread of this evil towards the fine wheat districts of the west:—

Therefore, in hopes to stop the progress of this scourge in our land, this Convention do most earnestly and confidently call upon and request the legislature now in session, to authorize the governor or some other suitable person or persons, to offer a reward to any person or persons who shall discover and make public any remedy for preventing or counteracting the effects of these insects. Such bounty to be paid out of the treasury of this State.

And whereas, also, a knowledge of the character and habits of these insects may lead to the discovery of a course of husbandry which may avoid the deleterious effects of the labors of these insects,

Therefore, this Convention do also request that the Governor may be further authorized and required to offer a reward for the best treatise on the habits, character and nature of these insects. Such treatise to be submitted to and determined by a board for that purpose to be appointed.

Gen. Clark offered the following resolution, which was adopted, and Messrs. J. B. Wakeman of New-York, C. Bergen and Gen. Johnson of Kings, P. Potter of Dutchess, J. J. Viele of Rensselaer, and A. Van Bergen of Greene, were appointed a committee to prepare the report.

Resolved, That a committee of six members of this Convention be appointed to prepare a Report on the future prospects of Agriculture, Manufactures and the Mechanic Arts in this State, to be illustrated by such statistics as the committee may deem appropriate, and that the Report, when completed, be published in the Cultivator, the Genesee Farmer, and the Journal of the American Institute.

Mr. Walsh of Rensselaer, offered the following resolution, which was adopted, and the committee appointed thereon were Messrs. Duane of Schenectady, Sacket of Seneca, Strong of Monroe, Allen of Erie, and Clark of Washington.

Resolved, That a committee of five be appointed to confer with the members of our Legislature on the expediency of making an appropriation of public moneys in aid of the improvement of our husbandry.

On motion of Mr. Fry of Montgomery,

Resolved, That this Convention recommend the holding of a State Agricultural Convention, in the Capitol, in the city of Albany, on the first Tuesday of February, 1840.

On motion of Mr. Buel,

Resolved, That the thanks of this Convention are due to Charles L. Fleishman, for his communication made to them, of his memorials to Congress, on the subject of a National Agricultural School, and on the history and improvements in the Beet Sugar business; and that a memorial to Congress, expressive of the desire of this Convention to favor the establishment of a National Agricultural School, from a portion of the Smithsonian legacy, be drawn up and signed by the officers of this Convention.

On motion of Mr. Allen,

Resolved, That the thanks of this Convention be given to the presiding officers and Secretaries, for their dignified and able discharge of the duties imposed upon them.

On motion of Mr. Youngs, of Tompkins,

Resolved, That Messrs. Buel, Cheever and Bement be appointed a committee for the express purpose of conferring with the Agricultural Committee of both Houses of the Legislature, upon the subject of the proposed reward, in relation to the wheat insect.

The Convention then adjourned *sine die.*

During the last day's meeting, a report was read by Mr. Buel, on the subject of the grain worm, and another report, by Judge Cheever, upon the improvement of common roads.

The gentlemen who principally participated in the discussions upon the adoption of the resolutions, were Messrs. Culver, Clark and Richards of Washington, Mack of Tompkins, Allen of Erie, Tiffany of Montgomery, Potter of Dutchess, Buel of Albany, Viele of Rensselaer, and Young of Tompkins.

Report on the Grain-Worm.

The committee designated at the last State Agricultural Convention, to continue the investigation in regard to the grain worm, report—

That since the last meeting it has been discovered, that there are two species of insects which depredate upon the wheat crop, viz. the *Cecydomia tritici* of Kirby, a yellow and apparently inert insect, not to exceed *one* eighth of an inch in length, and an unnamed creeping thing, *three* eighths of an inch long. The first, which was noticed in last year's report, preys only upon the grain in its milky state, or upon the pollen of the grain; the latter is said to prey upon the ripened grain, and to be found among it in great quantities when passed through the fanning mill. The first appeared ten to twelve years ago, near the borders of Canada, and has been extending annually since, east, west, north and south. The latter has been seen occasionally for several years, and during the last year has been found in great numbers in the wheat crops of West New-York and Northern Pennsylvania. The former is believed to be far the most injurious. The two insects have been so confounded, in the accounts of their depredations, that it is difficult to discriminate, or to determine the extent to which each has spread among us.

In their former report upon the grain-worm the committee quoted from Kirby, the entomologist, that the insect first makes its appearance "under the form of an orange coloured gnat, which introducing its long retractile ovipositor into the centre of the corolla, there deposits its eggs. These being hatched, the larvæ, perhaps by eating the pollen, prevent the impregnation of the grain, &c." and the committee added, on the authority of Prof. Low, that the progeny feed upon the young grain; that they are very small, from two to fourteen being sometimes found in one grain; and are distinguished by being of a bright orange colour; that they *do not extend beyond the grain in which they are born;* that the larvæ, after a period, fall down to the earth, in which they burrow, and remain there until the following summer when they ascend from the earth in the form of the beautiful fly, or gnat, which has been mentioned. The committee will make a further quotation in regard to the habits and depredations of the *Cecydomia tritici* from the recent edition of Loudon's Encyclopædia of Agriculture.

"The wheat-fly generally makes its appearance about the end of June; and according to the evidence of Mr. Sheriff they exist about thirty-nine days. The hue of the fly is orange, the wings transparent, and changing colour according to the light in which they are viewed. It lays its eggs within the glumes of the florets, in clusters varying from two to ten, or even to fifteen, and the larvæ feed upon the grain. They are produced from eggs in the course of eight or ten days; they are first perfectly transparent, and assume a yellow colour a few days afterwards; they travel not from one floret to another, and forty-seven have been numbered in one. Occasionally there are found in the same floret, larvæ and a grain which is shrivelled, as if deprived of nourishment; and although the pollen may furnish the larvæ with food in the first instance, they soon crowd around the lower part of the germen, and subsist, in all probability, on the matter destined to form the grain. Mr. Gorrie estimates the loss sustained by the farming interests, in the carse of Gowry district alone, by the wheat-fly, at £20,000 in 1827; at £30,000 in 1828; and at £36,000 in 1829."

Such as above described is precisely the appearance of the fly, of its larvæ, and of its habits and depredations, that have fallen under our observation; and although your committee think it has extended as far west as the Genesee valley, they are in doubt whether it has been there identified as the wheat destroyer. So far as our observation has extended, the insect is but seldom found in the wheat ear at harvest. The chairman sowed a sample of early May wheat, received from Gen. Cock, of Virginia, late last fall, and another early this spring. He watched it daily and narrowly on its coming into head. The small fly or gnat was seen in great numbers upon it before and after sunset. The heads were filled with larvæ, hardly a kernel in fifty escaped; and yet, on gathering a bundle of the straw at maturity, there was hardly found an insect remaining in the wheat heads.

The committee are happy to be able to confirm, in a measure, the truth of the intimation given in their last report, viz. that late sown spring wheat will escape the ravages of the worm. By late sowing they mean from and after the 20th May at Albany—earlier at the south, and later at the north, according to latitude and altitude, or the forwardness of spring vegetation. They give the following in proof of the correctness of this conclusion.

All wheat sown before the tenth of May, that came under their observation last summer, was more or less injured by the worm. All that was sown after the 20th of May escaped its ravages. Of that which was sown between the 10th and the 20th, some escaped injury, and some was considerably injured. One of the committee sowed Italian and tea wheat on the 16th. The fly was seen upon it for a few days after it came into head; though no material injury to the crop was perceptible.

An excellent and observing farmer in Wallingford, Vt. nearly 100 miles north of Albany, sowed parcels severally on the 25th of April, on the 19th and on the 25th May. The first sown was virtually destroyed by the worm; the second partially so; while that sown on the 25th May entirely escaped, and was a full crop.

The committee will close their report by quoting from a letter to one of them, from an intelligent Scotch farmer, Mr. Robert Forsyth, residing at Champlain, the northern town in our state, who seems to be an accurately observing man.

"1833. Sowed my wheat the 7th of April, the first season the worm was discovered in this part.

"1834. Sowed on the 15th April. The worm destroyed more than they did last year.

"1835. Sowed the 7th May. Wheat all destroyed by the worm. Some farmers in the neighborhood burnt their straw on the ground. Reserved an acre and a half, which I did not sow till the 24th of May; which gave a good crop—no worms.

"1836 and 1837. Sowed both years on the 24th of May—no worms.

"1838. Sowed on the 14th and 15th of May. A few worms observed. All wheat that I examined this season, had worms, less or more, in it, some half destroyed. Since 1833 I have examined every patch of wheat in the neighborhood, and some in the adjoining towns, and every patch sown before the 18th May had more or less worms—all sown about the 1st of May, very much destroyed. I have found the same worm in barley, oats and rye, and in herdsgrass (timothy) also.

"In June, 1834, as the ear began to form in the blade, I opened a number every day. I began to do so on a Monday, but I did not note the day of the month, which I think is of no consequence.

"For the first seven days, I could observe nothing in the heads prognosticating the worm.

"Monday the 8th day of observation. The ears nearly all out of the blade—observed nothing.

"Tuesday and Wednesday—nothing.

"Thursday. I thought I observed something like a small speck of fluid matter on some of the grains in the ear.

"Friday. The matter was more visible.

"Saturday. It was very plain to be seen.

"Sabbath day. Appeared yellow, but still a fluid matter.

"Monday. Appearance much as yesterday.

"Tuesday. The matter appeared more thick—colour yellow.

"Wednesday. It appeared like worms, but not very plain.

"Thursday. Perfect worms as I have ever seen since. I counted nine in one grain, and seventy in one ear."

Mr. Forsyth concludes his letter by saying, that the worm falls from the ear to the ground, and comes forth next season a fly, as he never could find any of the worms in the ear after the wheat was ripe.

J. BUEL, *Chairman.*

Report of the Committee on Common Roads.

The committee, appointed at the last State Agricultural Convention, upon the subject of improving our public highways, respectfully report:

That amongst the various improvements which have been carried forward in this state, that of improving our public highways, has been much overlooked. There are some reasons why this is not much to be regretted. Had their improvement been extensively entered upon, before the construction of our canals or our rail-roads, it is probable that much money would have been expended, which the construction of these works would, to a considerable extent, have rendered unnecessary. For instance, had a McAdam road been made from Albany to Buffalo, to carry freight, as is the case over many parts of England, the construction of the Erie canal would, for that purpose, mainly have superseded its usefulness.

So, also, had such a road been constructed for the transportation of passengers by post coaches, the rail-roads now completed and going forward in that direction, would have rendered it, to some extent, a useless expenditure. Wherever, therefore, canals have been made, or are to be made, for the transportation of freight, or rail-roads for the transportation of freight and passengers, the improvement of the public highways, for the accommodation of the long freight or the long travel, is of less importance.

As our public highways, so far as they relate to our agricultural interests, are to be connected with our canals, the committee think it not impertinent to refer to that branch of our public improvements. In casting our eyes over the state, it will be found that very much has been done.

It is now 21 years since the commencement of the Erie canal. That important work, extending from nigh the eastern boundary of the state to the western, has long since been completed.

At Utica, less than 100 miles from Albany, the Chenango canal runs off at right angles, and parallel with the Hudson river, nearly to the line of Pennsylvania.

At Montezuma, 95 miles further west, the Cayuga and Seneca canals bring the borders of Cayuga and Seneca Lakes to canal navigation.

The Crooked Lake canal, passing from Seneca Lake westward to Crooked Lake, opens the shores of the latter to a like navigation.

The Chemung canal, commencing at the southern termination of Seneca Lake, extends canal navigation south to the Chemung river, nigh the line of Pennsylvania again.

At Rochester, 64 miles further west, the Genesee Valley canal, now constructing, carries canal navigation over to Pennsylvania at Olean.

Again—at the north, the Champlain canal carries a similar navigation to that lake and to the Canada line.

At Rome, 110 miles from Albany, the Black River canal, now constructing, leaves the Erie canal at right angles, and runs off northerly to Lake Ontario.

At Syracuse, 50 miles further west, the Oswego canal leaves the Erie again, and reaches Lake Ontario in 38 miles, at Oswego.

It may, therefore, be asserted, that there are comparatively but few cultivated farms in this state, whose produce, when made, is more than one day's drive, with a horse team, from canal or tide water. And it is gratifying to know, that these improvements have been so made, and hitherto so conducted, as to furnish the means of their own support, and will ultimately pay the expense of construction, without leaving a debt chargeable upon the taxable property of the state.

It is believed that lines of rail-roads will, at no distant day, be constructed from New-York, crossing the lateral canals, through the southern counties, to Lake Erie.

From New-York, by the way of Albany and the Erie canal to Buffalo.

From Albany and Troy, by way of Saratoga, to Lake Champlain at Whitehall, and probably from Lake Champlain to Ogdensburgh.

England has expended her millions of pounds in McAdam and paved roads, for which vast improvement she is often triumphantly referred to. But what she has done in such roads, is now already done and soon to be done for us in the shape of canals and rail-roads.

The improvement of our public highways, therefore, so far as they relate to the transportation of our produce and merchandize, or the accommodation of our public stage travel, will be mainly to connect the improved parts of our country with our canals and rail-roads; very much remains then to be done.

Our public highways are generally laid at an early period in the settlement of the country, when but little attention is paid to their grade. The settler selects the most eligible spot for his house, and then arranges to bring the road to it, and frequently without reference to general direction or elevation. The inconvenience of travelling over crooked and hilly roads follows, and we see it submitted to long after the wealth and business of the country demand their improvement.

The market towns of our farmers are distributed over the state, at the most accessible points on the canals or rail-roads. To these points should our public highways be directed and improved.

The value of the produce of a farm, and of course of the farm itself, so far at least as relates to the surplus, depend upon the price in market, and the expense of placing it there.

The produce which requires a team to travel one day to market, and another to return, is worth to the owner about $5 per load less on the farm than in market.

If, therefore, by the improvement of his market road, he can carry 24 hundred where he now carries 16, or 30 where he now carries 20, he will save $2.50 on every load he takes to his market. If his farm produces ten loads, he saves $25 per year.

The one-half, or even the one-fourth of this sum in a town or county tax, judiciously laid out in the improvement of his market road, would soon place it in a condition to reduce the expense of transportation in the above proportions.

The first step to be taken towards such improvement should be, so to change the line of the road as to bring it as nigh as possible to a level grade. To go round the hills instead of going over them, for distance is of but little consequence in the transportation of tonnage, compared with elevation. But in many instances, both distance and elevation may be saved by the proper laying of the road.

The laying out or altering of highways, is now confided to a board of commissioners, annually elected in each town.—The principal roads of a town cannot be materially changed in their lines, without interfering more or less with the private interests of some of its inhabitants. This would in many instances create an interest which would displace a board of town commissioners, who should fearlessly attempt to discharge their duty in a way best to promote the public interests. Besides, it would be necessary in many, and perhaps most instances, to extend the alterations or the new lines through several towns. In that event, the benefits of the improvements in one town, might be defeated by the refusal of the next to carry them forward.

These objections could be obviated by the appointment of a board of commissioners of highways for each county, or for each senate district, either by the governor and senate, or by election, who should hold their offices for three or five years. It should be their duty, upon the application of a certain number of freeholders in any town to examine the country where a new road or an alteration of an old one is proposed, and if, in their opinion, the public good required it, they should lay out, or alter any public highway in or through any town or number of towns in their district. And where the benefits of the road are mainly confined to the town, let the expense be assessed upon the town, but where they are extended to the whole county, then upon the county.

Such commissioners should be authorized, if they deem it necessary, to employ suitable engineers to aid in laying out such roads. Such roads, when laid out, should be opened and worked under the direction of the commissioners or one of them. This is an important step towards obtaining good roads, and should be first taken. A suitable sum of money should be raised by the town or county, as the case might be, to be expended in opening such road, and placing it in a good condition for travel.

Let a suitable sum of money be annually raised in each county, and placed in the hands of such commissioners, to be expended in facing such roads, and the other principal market roads in each county, with broken stone or coarse gravel, of sufficient width for one team or more, according to the amount of travel upon the road. Such foundation could be made to the width of eight to ten feet, at a moderate expense, almost any where, and a foundation of that width, well imbedded and shaped to correspond with the adjoining surface of the road, and kept in repair, would always secure a good track for one team, which would be sufficient in most cases. The turning out of wagons to pass each other, would not cut up the parts of the road not imbedded so as to injure its usefulness.

This hard facing should be commenced upon the parts of the road most travelled, which would generally be nighest the market town, and carried back as the means furnished would permit. In this way, every person contributing to the expense of the improvement, would share at once in its benefits.

If the principal roads in each county were placed under the control of such board of commissioners, and an annual fund put in their hands, to be raised by a light tax, and to be expended in laying out, altering, grading, draining and facing the roads in a proper and economical manner, our principal roads would immediately put on a different appearance.

The farmer would find an ample equivalent for his tax, in the reduced expense of taking his produce to market, and every body else in the comfort and convenience of good roads in their various errands of business or pleasure.

The ordinary repairs of the common and more domestic roads of each town, may be left, at least for the present, to the management of the present town commissioners.

The committee take this occasion however, to remark, that the present mode of assessments of labor for the repairs and improvements of our common roads, has, for the amount nominally expended, produced but little beneficial effect. The committee do not believe they exceed the fact, when they say, that one-fourth the amount in cash, expended by skilful and faithful hands, would produce more effect than the present expenditure. And could our farmers feel the force of the maxim that "*time is money*," it is believed they would cheerfully submit to the payment of the lesser amount in money rather than the larger in labor. But as this branch of the subject—that is to say, the repairs of the less important roads in each town by the town commissioners—is not necessarily connected with what is deemed of the greater importance, to wit—the improvement of our more important and market roads, under the plan above suggested—the measures should be kept distinct. The success of one should not be made to depend upon the fate of the other.

To show the comparative expense of drawing one ton over one mile, at different rates of acclivity, by a stage coach and by a wagon, the committee give the following table, furnished by John McNiel, Esq. civil engineer, to a committee of the House of Commons of Great-Britain, on the 12th of October, 1831. By this table, it will be seen, that it costs to carry in a wagon, upon an ascent of 1 foot in 10, or 5 degrees and 42 minutes elevation, 52d.07; and upon an acclivity of 1 in 15, or 3 degrees and 40 minutes, 28d.70. Whilst upon an acclivity of 1 in 60, or about 1 degree, it costs 15d.20—that is, it costs about one-half as much to transport over a road of one degree in its acclivities, compared with one of three and a half degrees; and less than one-third upon a road of one degree, to that upon a road of five and a half degrees, and the expense still diminishes as we approach to a level.

Four horse stage coach, average speed ten miles per hour.		Wagon and four horses, average speed two and a half miles per hour.	
Rates of acclivity.	Pence and decimals.	Rates of acclivity.	Pence and decimals.
	d.		d.
1 in 10	77 24	1 in 10	52 07
1 15	57 78	1 15	28 70
1 20	50 44	1 20	22 83
1 30	44 15	1 30	18 55
1 40	41 25	1 40	16 76
1 50	39 56	1 50	15 82
1 60	38 46	1 60	15 20
1 70	37 68	1 70	14 77
1 80	37 09	1 80	14 46
1 90	36 64	1 90	14 22
1 100	36 28	1 100	14 04
1 150	35 19	1 150	13 46
1 200	34 64	1 200	13 18
1 300	34 09	1 300	12 91
1 500	33 65	1 500	12 69
1 1000	33 32	1 1000	12 53
Horizontal	32 98	Horizontal	12 36

By this table, it will be seen, that we have no cause to regret that we have made canals instead of stone roads, for the transportation of our freight. The last item in the table shows that it costs 12.36 pence sterling, or about 25 cents, to transport a ton a mile on their stone roads, whilst upon our canals it does not exceed one-sixth that amount.

There are many roads in this state, over which considerable tonnage is carried, and over which post coaches are drawn, whose acclivity is as high as five degrees. In a large proportion of such instances, a skilful board of commissioners could so lay out a road as to reduce the ascent one-half or two-thirds. The committee believe there are more or less important roads in almost every county in this state, whose lines may be so improved, and whose beds may, at a moderate expense, be so formed, as to reduce the expense of transportation upon them fifty per cent, and add an equal proportion to their convenience and safety in travelling upon them for business or pleasure.

S. CHEEVER, *Chairman.*

Albany, February 6, 1839.

N. Y. State Agricultural Society.

The society convened, pursuant to adjournment, at the City Hall, in Albany, on the first Tuesday in February, 1839, Alex. Walsh, Esq. of Rensselaer, in the chair, and James L'Amoreux, Esq. Secretary *pro tem.*

Mr. Buel read a letter from Dr. L. C. Beck, transmitting a resolution of the board of Geology, appointing Messrs. Beck, Emmons and Hall a committee to confer with the State Agricultural Society, in regard to the points especially worthy of attention in the examination of the soils of the state. Whereupon it was

Resolved, That Messrs. Nott, Beckman, Buel, Rotch, Cooper and Spencer, of Madison, be a committee to confer with the state geologists on the matters above referred to.

It was resolved to reduce the annual payments required from the society from two dollars to one dollar.

The annual report of the Treasurer was read and accepted.

Messrs. Buel, Allen, Viele, Van Bergen and Spencer were appointed a committee to report the names of officers of the society for the coming year, who after consultation reported the following, and the report was adopted.

ANTHONY VAN BERGEN, of Greene, *President*

W. A. S. North, of Schenectady, J. S. Spencer, of Madison, Alex. Walsh, of Rensselaer, E. Smith, of J. B. Nott, of Albany,	*V. Presidents.*

J. Buel, *Corresponding Secretary,*
William Cooper, of Albany, *Secretary.*
C. N. Bement, of Albany, *Treasurer.*

John Townsend, Jesse Buel, and James L'Amoreux, of Albany, H. D. Grove, of Rensselaer, and L. F. Allen, of Erie, *Executive Committee.*

Mr. Buel read a communication from C. L. Fleischmann, accompanied with two memorials to Congress, one for the establishment of a National Agricultural School, and the other containing interesting and valuable data in regard to the culture of the sugar beet, and the manufacture of sugar therefrom

On motion, it was resolved, that the thanks of the society be returned to Mr. Fleishmann for his communication, and that Messrs. Nott, Buel and Potter be a committee to memorialize Congress for the establishment of a National School of agriculture, from a portion of the Smithsonian legacy.

The society then adjourned to meet in the Assembly Chamber at 4 P. M.

Assembly Chamber, 4 P. M. February 5.

The society met pursuant to adjournment.

The annual address was delivered by John J. Viele, Esq. of Rensselaer.

Mr. North then presented a report, *on farm yard management, as it relates to the wintering of cattle, and the augmentation of manures.*

Mr. Rotch presented a report *on the feeding and management of sheep in winter.*

Mr. Buel presented a report *on the best vegetable or root crops for feeding cattle, and the best manner of cultivating the same.*

Mr. Bement presented a report *on the most profitable mode of fattening pork and rearing swine.*

Mr. Allen presented a report *on meadow and pasture lands, and the best mode of renovating them, and seeding down lands to grass.*

[The address will be published as early as our limits will permit with the aid of an eight page supplement.]

The society then adjourned to meet at the City-Hall at 10 o'clock to-morrow morning.

City-Hall, February, 6th.

Messrs. North, Grove, Fry and Nott, being appointed to designate subjects to be reported upon at the next meeting of the society, reported in due time the following :—

1. On the most approved method of stall-feeding oxen and other neat cattle. [Committee Wm. H. Strong and Samuel Clark, of Seneca county.]
2. On converting green crops and other vegetable matters into manure. [Committee, Messrs. Ball and Walsh, of Rensselaer.]
3. On the tillage proper for the different kinds of soils —as clay, sand, gravel. [Each soil to form the subject of a distinct report, and J. P. Beekman to report on gravel, A. Van Bergen on clay, and J. Buel on sand.]
4. On the proper time to cut timothy and clover, and the most approved method of curing the same. [Committee, A. Van Bergen and W. Salisbury, of Greene co.]
5. On the effects of lime, and its application to different soils. [Committee Messrs. Buel, Viele and Mather.]
6. On the best means of eradicating the Canada thistle. [Committee, Messrs. North and Duane.]
7. On the manufacture of sugar from beets. [Committee, Messrs. Wardwell and Marshall of Jefferson, and Cheever, of Albany.]
8. On the comparative economy of employing oxen and horses in the usual business of the farm. [Committee, Messrs L. F. & R. L. Allen. of Erie.]
9. On the best mode of cultivating the potato. [Committee, Messrs. Buel and Whiteside.]

10. On the comparative value of potatoes, ruta baga and mangold wurtzel, as food for cattle and sheep. [Committee, Messrs. Grove and Rotch.]

11. On the value of apples for neat cattle, sheep and hogs. [Committee, Messrs. Grove, Ball and Armstrong.]

On motion of L. F. Allen,

Resolved, That J. B. Nott, C. N. Bement and Volkert Bullock, be a committee to examine such agricultural implements as may come under observation, and present their views of the utility of the same at the next annual meeting of the society.

On motion of Mr. Allen, Messrs. Allen, Buel and Nott were appointed a committee to memorialize the legislature, in behalf of this society, to pass a law for the improvement of agriculture, in accordance with the report and bill introduced by the committee on agriculture at the last session.

On motion, it was resolved, That the Hon. Ambrose Spencer, Paraclete Potter, John P. Beekman, Anthony Van Bergen, and J. B. Duane, be appointed a committee to take into consideration, and to report at the next annual meeting of the society, the present state of the silk business in the United States, together with such information and recommendations for public use, as may best, in their judgment, promote its future increase and prosperity.

On motion, it was resolved, unanimously, that the thanks of this society be presented to John J. Viele, Esq. for his interesting and highly valuable address, delivered yesterday before the society in the Assembly Chamber; and that Gen. Clark and Judge L'Amoreux be a committee to present the thanks of the society to Mr. Viele, and to request a copy of the address for publication.

Resolved, That the thanks of the society be given to the presiding officer, for the able and dignified manner in which he has discharged the duties of the chair.

The society then adjourned to the first Tuesday in February, 1840.

On Farm-Yard Management.

The committee to whom was assigned the duty of furnishing an essay on the above subject, have the honor to report as follows.

As the business of farming is one of the utmost importance to the community, it is not only necessary that those engaged in it should be well acquainted with the theory, but also with the minutia of the practice in all its forms, and he who farms it on theoretical principles alone, will in nine cases out of ten be most wofully disappointed in his calculations.

Our subject involves one of the lesser branches of this art, and may be said to be, that sort of management that relates to the business of wintering the different kinds of domestic animals, and the making and preserving the best and largest quantity of manure to be derived from them.

Whatever can contribute to the former, either as to their accommodation or subsistence during the winter, and to the latter as to the quantity and quality of the manure, is of the utmost consequence. Upon the good order and economy of the farm yard and buildings, and the care and attention bestowed, depend in a great measure the health and thriftiness of the stock, and the vigor and productiveness of the land to be manured by them.

To compass these ends, farm buildings should be put up with a view to convenience in foddering out the hay, in accommodating the stock, and in taking care of the manure.

On grazing farms, good roomy sheds, facing the south and east, are absolutely necessary. In proof of which it may be stated, that on farms, not overstocked, and where fodder is abundant, cattle may be wintered as well under open sheds, as they would have been if housed, and better than they would have been, if tied up in the cold open ricketty stables of the slovenly farmer.

The yard should be divided into as many compartments as there are different kinds of stock, and different grades of the same stock, to be wintered; that is to say, the young stock should be separated from the old, and the calves from the young stock and yearlings—thus subdividing them, they are not restive, but feed quietly and do better. Sheep, which are kept to some extent by all our farmers, should never be suffered to run with the neat stock, they are liable to be hooked, to lose their wool and be defrauded of their provender. They should have a comfortable shed, furnished with racks, troughs, and a yard proportionate to their number.

The common practice of watering stock at an adjoining pond or brook is not a good one. If there should be no spring in the vicinity which can be brought into the yard, a well should be dug and furnished with a pump, whence the water might be led by conductors into each yard, and the cattle, sheep, &c. might drink as often as they pleased; it is said they will drink half a dozen times a day, when the water is at hand. In going some distance to water a great deal of manure is lost, and in cold boisterous weather they will suffer thirst a long time before they go at all.

To keep the yard dry, and to preserve the liquid manure, there should be a shallow basin in the middle of it, into which all the weeds, parings of the road side, old rubbish, and every thing that will make manure, should be deposited; these being well mixed with the stalings of the cattle, make a strong and rich compost which answers well on grass lands. By following up this practice during the summer and fall a great amount of good manure may be obtained. A farm yard kept dry and well littered with straw, keeps the stock clean and comfortable, and by absorbing the moisture, is converted into manure, and adds greatly to the dung heap.

As soon as the foddering season arrives, the cattle should be brought up and folded in their respective yards during the day, by which practice lots of manure are saved, which would otherwise be scattered abroad and lost—at night they are tied up, with chains or ropes in a well ventilated but warm stable, the floor of which should have descent enough to carry off the stalings of the animals into the gutter behind them, and be thence carried into a receptacle prepared for it, or if there be no such place, into a heap of manure which may at least retain a share of it.

It is said that neat stock thrive better, and consume less fodder when stabled, than when left to take their chance in the barn yard. It is certain they do not waste so much. But it is necessary, in order to reap the advantages to be derived from stabling them, that the stables should be warm and the stalls roomy and well bedded with straw, that the curry comb or card be applied every morning, and that a portion of carrots, potatoes or turnips, be allowed them daily; and here let it be remembered, that it is the interest of every farmer to keep his stock in as high condition as possible—the cows will pay for it when the milking season comes, and the young stock will sooner get their growth and be saleable at any time.

It has not in this country been the practice of our farmers, to raise root crops expressly for the purpose of feeding store cattle during the winter. Feeble attempts are only now being made to introduce the cultivation of turnips for sheep, but it is hoped that a new era of better husbandry is beginning to dawn upon us, and that farmers will ere long see the necessity of growing all coarser, but invaluable root crops; the liberal feeding of which during the foddering season, will be sure to keep their stock in a progressive state of improvement, besides lessening the consumption of hay and grain. In wintering young stock and yearlings it is not customary, nor indeed is it necessary to tie them up in stalls; a good warm shed well littered for them to lie under, abundance of good hay, with a little corn or a few roots daily, will keep them in a growing state, and having the run of the yard, will always present a clean healthy appearance.

In bringing calves through the winter it is necessary to be more careful than with any other species of stock. The common practice of giving them a little skimmed milk or whey from the cheese tub, during the summer, with what grass they can get in a paddock, is not enough to put them in a condition to bear our cold winters with impunity. They should be taught to eat a little oil cake, or ship stuffs, or meal of any kind, which will keep them growing and generally healthy. If at any time, they are attacked with purging, which is a common disease with them, as either too much or too little feed will bring it on, a little chalk or ashes mixed with their meal will generally remove it. In the cold wet storms of the fall of the year it is highly proper to house them, the strongest and thriftiest apart from the weakest; during the winter they should be fed with roots of some kind or other, morning and evening, and at noon with ship stuffs mixed with ground oats. This way of bringing calves through the winter, may be thought to be rather extra and expensive, but it is not so, for when a year old, they will be as large and far more likely than the common half starved animal of twice the age. Upon turning them out to grass in the spring, it will not be advisable to discontinue their accustomed supply of meal or bran on a sudden, it ought to be done gradually, and as their natural food increases, they will learn to do without it.

There are various other small matters, relating to the good order and economy of the farm yard in the disposition of stock, other than neat cattle, which we will mention before quitting this part of the subject; much of what has been said of them will apply to horses; all they require is to be kept clean, well fed and well worked.

Sheep, as has been observed, should have a yard and shed to themselves, and supplied with water. The fashion of compelling them to eat snow in order to quench thirst, is a bad one and ought to be abandoned. Turnips or some other vegetable should be allowed them during the winter, and these roots are particularly useful to them as the lambing season approaches If a portion of the flock should be weak and sickly they should be removed and put by themselves, and meal or ground oats given them in addition to their ordinary food. The ewes about lambing, should also be separated from the flock; they will be more likely to save their lambs, and if young ewes to own them.

The shed should be well littered with straw and kept dry, and as wet and moisture is deleterious to them, they should always be brought up and housed in stormy weather. Salt should occasionally be given them; as it should also to all the stock indiscriminately.

It will be seen then from what has been said, that all that is necessary to bring a man's stock through the winter in a thriving condition is to keep them clean and warm, and to give them abundance of food and water. In many cases the common mode of wintering stock on dry hay and drier straw may be attributed to ignorance The great body of our small farmers whose habits and situation in life do not lead them to acquire information, seem to think the great art in wintering their stock, consists in getting them through with the least possible quantity of provender. A saving disposition with a view to present profit appears to animate the whole fraternity, while a liberal expenditure, holding out certain promises of ulterior benefit to them, seems to meet with no favor. Their sole object is to force a living out of the earth some how or other, regardless of the good to be derived from adopting the improvements daily making in every branch of farming. They go on in the old track of their fathers, and transmit the same nearly unchanged to their children.

In the business of saving manures they are equally remiss; the forming of composts, and manfacturing large quantities of manure by mixing the various vegetable matters with topsoils, with lime and with mud, is seldom or ever thought of.

To save the greatest quantity of manure, and to preserve it from losing its strength, it should be protected from the weather. If this cannot be done under cover, it is advisable to stack it, so that it will shed rain, and escape the dissipating effects of the sun and the wind; during frosty weather it will lose none of it virtue, but in the spring, the stacks must be attended to, and as the bed of the farm yard feels the influence of the sun and begins to thaw, the manure should be scraped up and added to the stacks; this should never be omitted, otherwise the strength of it runs off or is dissipated, leaving nothing but the unfermented straw behind. Any means that will save it from being leached by rain should be adopted, and in addition, and to prevent the yards being flooded by heavy rains, the buildings adjacent to it should be furnished with gutters and drains to lead off the water; without these precautions a great share of the manure in every barn yard will be exhausted of its best properties before it is applied to the land. It is not uncommon to hear farmers complain, that manure has little or no effect on their land. And such manure as some of them make, which has lain for months exposed to all the vicissitudes of the weather, can have no effect. Perhaps it is drawn out in the winter, spread abroad in small heaps, and not turned under till nearly all its useful properties are extracted by frequent washings. Now nowithstanding the great value of manures to the farmer, the increasing, preserving and judicious employment of them seems to be a secondary object: considerable quantities are daily lost about every farm, and what is collected is of little value owing to the manner in which it is treated. No farmer can expect to succeed in his agricultural operations without the aid of good manure and plenty of it, still its augmentation and preservation seems to be little cared for; provided his barn yard is cleaned out once a year, he thinks he has done enough.

It is feared that advances in this branch of farming, in common with others, will not be very rapid until our rulers, influenced by the true principles of a wise political economy, shall see fit to do something for the cause. The rage for speculation and the desire to gather riches too fast, which but lately filled the whole community with golden dreams, has in a measure subsided, and peoples minds now being sobered down to realities of life, they are willing to go to work for a living. It seems then, there never was a time when the fostering care of the government might be extended to the interests of the farming part of the community with a better prospect of advancing the permanent good of the whole than the present.

The art of farming in all its various details, is an employment requiring constant care and attention, as well as judgment in bringing its operations to a successful issue.

It is the great employment of the rank and file of the country, and as such deserves to be considered by our rulers, and were they seriously to entertain the purpose of encouraging it, the zeal of its followers would be sharpened and their efforts redoubled to place this science, to which our country owes so much of its prosperity, upon a proper footing. Committees of agriculture, it is true, are appointed year after year, in our national and state legislatures, to watch over its interests, but what have they done for the cause which feeds and clothes them. The silk business may have been talked over in the former, and the Canada thistle choked in the latter, but no important measure for its encouragement has been passed, at least of late years. Every other great interest of the country seems to have been cared for but the one under consideration; commerce, manufactures, education, civil and military, the fisheries, &c. are all bountifully endowed by government, while for the benefit of the profession, to which the great mass of the people belong, there is no board formed, no school house raised, nor bounty for its amelioration or encouragement offered. Is it neglected by our rulers, because it is less useful or needs less help than others? It has, to be sure, by its own life supporting power, felled the forest of the west, and converted the howling wilderness into fertile fields; but it has not yet succeeded in rendering us independent of other nations, for the very staff of life. The fact alone, that bread stuffs to a large amount were lately imported from abroad, and potatoes are even now being imported from Nova Scotia and elsewhere, would seem to call upon the government in the loudest terms to embrace the patriotic as well as popular measure of encouraging agriculture. Individual enterprise has done much for the cause, by disseminating among us by means of periodicals, the results of experiments and good advice in every department of farming. But these means of information are very limited in their circulation. The attachment to old habits, the dislike to book farming, and the utter ignorance of what is going on in the agricultural world, are also serious drawbacks to improvement; which it is feared, nothing can remedy but the formation of agricultural societies in every county of the state, under the patronage of the government.

Under such a system, the results of good farming and an improved state of culture, would be brought home to every man. Knowledge would be more generally diffused, and great improvements consequently made in every branch of rural economy. Discoveries in agriculture are continually making, and must continue to be made ad infinitum, for no limits can be assigned to the capabilities of the earth, in producing the necessaries as well as the luxuries of life. There seems to be no end to the improvement of the qualities and perfections of domestic animals—yet how few of our common farmers are aware of these facts. They know little or nothing of the principles of vegetation, or of the management and effect of the different kinds of manure, nor have they any very clear ideas on the subject of breeding the different kinds of domestic animals.

Until a spirit of emulation is aroused by means of agricultural societies this state of things must continue. To get up such a spirit, has been and is the aim of the agricultural society of this state. It has thus far struggled through a feeble existence, upheld alone by the exertions of a few spirited individuals, headed by the patriotic and intelligent editor of the Cultivator. Under better auspices than we have yet had cause to boast of, the society might flourish and be productive of incalculable good—but unless a favorable ear is turned to our petitions for aid to the cause, there is reason to fear that after this meeting, it will be adjourned to meet no more. W. AUG. S. NORTH, *Chairman.*

Report on the mangement of Sheep.

Your committee, on "The feeding and management of sheep in winter," while they are fully aware of the importance of the subject thus brought under their notice, feel, that though they can suggest but little that is new and instructive to the intelligent farmer or flock-master, in the home management of sheep as now practised, yet are inclined to believe there is much, both interesting and useful, which may be gathered from a knowledge of sheep husbandry in other countries, where its vast importance, (forming as it does, in some cases, the very wealth of the nation,) has called to its aid all that education, science and close observation could suggest for its improvements; and there are instances where this valuable amount of intelligence has been practically applied in this state, with a success that warrants your committee in offering some suggestions from the German practice, that may materially improve the winter management of sheep in this state.

The main body of sheep in the northern and middle states produce wool of an improved quality, being more or less mixed with the Merino, or the improved Merino of the Saxony family, and are principally kept for their fleece; the carcass being a secondary consideration; but within a few years this has become more valuable, from causes which it is not necessary here to examine, as they are self-evident to every observing mind. Your committee would therefore have it understood, that their attention on this occasion has been nearly confined to the management of the Spanish sheep in all its various grades, as found in this country.

Many plans have been recommended, rules have been prescribed, maxims laid down, and the requisite quantities of food stated, for maintaining a sheep in thriving and good condition. But all these can only be relatively understood, for we ought to take the size of the animal into consideration; and it must be borne in mind, that a large sheep requires more food than a small one, and that a sheep which gives five or six pounds of wool, must consume more than one which gives but three pounds.

These considerations lead to a proposition which has received but little or no attention from the great mass of our farmers who keep sheep, namely:

The influence or effect of feed on the quantity and quality of the wool and carcass.

It may be laid down as a rule, that two pounds of good hay, or its equivalent in grain, roots and straw per day, fed regularly at three fodderings, are sufficient for a grown sheep of the Merino family, producing three pounds of fine wool, provided it enters winter quarters healthy and in *good condition.* For breeding ewes, or a larger race of sheep, this quantity would not be sufficient; and for a race by nature small and weak, it would be more than they require, and if fed to them would greatly diminish the quality of the wool, though it increased its quantity.

Farmers in Germany generally allow their sheep an average of from one and three-fourths to two pounds of hay daily, including the whole flock, and their sheep are vigorous, healthy and in good condition, and attended with the best effect upon the wool. Others allow their sheep one and a half pounds daily, and they do not suffer by this quantity, but are healthy and rather thriving upon it; still they do not yield so much wool, nor is the carcass so heavy; while others, through ill-advised economy, limit their sheep to one and one-fourth pounds of hay daily; but it was found that they sheared from ten to sixteen ounces less of wool per head; that the constitution of the animal could not be matured, and he ultimately became a diminutive and feeble animal. The wool from such sheep is termed "*hungerfine,*" and appears to possess a high degree of fineness upon the sheep's back, and is extremely mild and soft to the touch. "But," says Mr. Elsner, a writer on sheep husbandry, "this kind of mildness is as exceptionable as its fineness, both arising from the poverty of the animal; for after shearing and washing, it lessens to an unusual degree in volume." It is deficient in strength, elasticity and the felting properties, and it does not make as perfect and durable a fabric, as it would, had the sheep been kept in a thriving condition. Its intrinsic value, therefore, to the manufacturer, is not so great as its apparent fineness would indicate, and the grower who anticipated a "good clip" of wool from his flock, is very unpleasantly awakened from his dreams, when he finds that they shear much less than he expected; and this we fear is too often the case with many of our economists who undertake to keep flocks of fine woolled sheep.

It is, however, certainly a most erroneous conclusion, that sheep produce an increased or extra quantity of wool in proportion to an increased or extra quantity of feed. "Farmers who were deceived by this theory," says Mr. Elsner, the author above quoted, "have been disappointed; for the increased quantity of wool was scarcely half in proportion to the extra quantity of feed, and the quality was considerably deteriorated." Such is the opinion of one of the most intelligent breeders and close observers of the economy of sheep in Germany. The experience of one of your committee fully goes to confirm the above position. And his experiments, made with great attention and exactness for a series of years, both here in and Germany, enable him confidently to offer the following result: That sheep of good size, superior fineness and thick fleece, when rightly fed and managed, produce on an average two and three-fourths to three pounds of clean wool, washed on the sheep's back. But a flock is only rightly fed and managed, when they are not allowed quite as much as they would eat, thus insuring thriftiness and bodily health. To effect this desirable object, as has been already stated, two pounds of good hay, or its equivalent in grain, roots and straw, per day, are required; whereas, the same sheep, were they allowed as much hay as they could eat, would consume over three pounds or its equivalent in grain, roots and straw. Now in order that the increased or extra quantity of wool be equal to the increased or extra quantity of hay, they ought to shear from four and an eighth to four and a half pounds of wool per head. But this is not the case: the increase seldom amounts to more than 25 instead of 50 per cent. In other words, six pounds of hay fed to three sheep produced from eight and one-fourth to nine pounds, while the same quantity and of the same quality, fed to two sheep daily produced from six and seven-eighths to seven and a half pounds of wool only, leaving a balance in favor of the former of from one and three-eighths to one and a half pounds; an item in the profits of a sheep establishment of some importance, especially where large flocks are kept. But this is not the only disadvantage of high feeding, for while it ruins the natural constitution of the animal, it injures the wool.

Some German writers on sheep husbandry estimate this reduction in quality at ten per cent, and maintain that the greater waste in cleansing it increases the loss to twenty per cent; such wool containing a larger quantity of oily or greasy substances, which go far to make up the increased weight of the fleece. Assuming this to be a correct estimate—and it is believed to be a fair one—it will be found that for an outlay of 50 per cent in extra feed, only five—at the most ten—per cent of wool is obtained in return. It would, however, increase the carcass and the quantity of manure, but this would be done at too great a price. If, however, the sheep were intended for the shambles it would alter the case.

Having considered the influence or effect of feed upon the quality and quantity of the wool, and shown that either extreme, *the too little,* or *the too much,* is unprofitable to the wool-grower, your committee will, in the next place, proceed to the consideration of the care and management of sheep during winter.

It may be classed under three heads—*Feeding, Watering* and *Shelter.*

Food—Should be such as to agree with the habits and economy of the sheep, and should contain nourishment and bulk equivalent to two pounds of hay.

The varieties of winter provender, to be considered, are hay of all the cultivated grasses, such as clover, lucerne, &c. &c. hay from natural but dry meadows; sound oat straw, barley, rye and wheat, well cured vetches and pea vines; all kinds of grain, but with the exception of the less healthy rye, roots, such as potatoes, carrots, ruta baga, mangold wurtzel, turnips and the different kinds of beets; all are conducive to the health, prosperity and internal economy of the sheep.

Of the different kinds of hay, white and red clover, sainfoin and timothy, stand first, and seem to be best adapted to the nature of the sheep; they eat it with great avidity, and with but little abatement in appetite through the whole of a long winter. Of red clover, there are two kinds, the northern and southern—the latter makes much the best hay. Sheep should be made to eat their hay up clean when it is cut at the right time and well cured, and that time is, when clover, lucerne and sainfoin is in full bloom, and timothy when about one-quarter to one-half of the blossom is off. But if the growth is large, lodged or decayed at the bottom, then they should not be forced to eat it clean; but an allowance must be made, as the decayed parts, were they compelled to eat them, would prove hurtful. And if hay is somewhat injured by rains during the process of curing, then again an allowance should be made. Mow burnt or mouldy hay should never be used in the sheep cot, for it causes a general debility of the system, and if continued would ultimately create the *rot.*

Hay from low land meadows is not so good as that from the uplands; if these can be renovated by occasional ploughing and reseeding, it improves the quality; but in portioning out the quantity of hay to sheep a suitable allowance should be made, and the more of the wild and sour grasses are mixed in with it, the greater should that allowance be.

Hay from wet meadows is not wholesome for sheep, and should never be given them unless from necessity; then double the usual quantity must be allowed. Were they confined to such hay and compelled to eat it nearly or quite clean, it would prove ruinous to the flock.

Hay from meadows that have been very highly enriched by top dressings, afford a luxuriance and rankness of growth possessing a laxative property, and should be dealt out to sheep very cautiously, especially to lambs, and if it is pretty freely salted with a view of preserving it, the greater caution is necessary. Sheep will then eat it greedily, especially if salt has been withheld from them for some length of time, but it is then the more dangerous; as foddering from it a few days in succession, even a few times, creates great thirst. Sheep drink an unusual quantity of water, and scouring is produced, which often proves to be very fatal.

But before entering upon any course of feeding, it is advisable to divide the sheep into different flocks. The breeding ewes into one flock — the wethers into another—and the lambs into a third. From these main divisions, subdivisions may be made as circumstances require, taking care that the individuals composing the different flocks, are as nearly as possible, of equal size and strength; if not, the weaker portion are not apt to get a due share of the fodder. And if there are any individuals that are old, feeble, &c. an invalid department ought to be added, and extra care and attention bestowed upon it.

Having all the different arrangements completed, a careful supervision must be extended over the whole, and the course of treatment regulated by circumstances.

Supposing the breeding ewes to be in good condition, they should receive one and a half pounds of hay and one and a quarter pounds of grain per day, until the rutting season is over; the grain must be then withheld and the flock go through the winter on hay, increasing it to two and a quarter pounds, and an occasional foddering of straw, until within five or six weeks of lambing, when it is decreased a little and roots substituted, commencing by degrees, with one bushel of potatoes, or one bushel and five-eighths of ruta baga to one hundred ewes, and increasing the quantity gradually, of potatoes to three bushels, and of ruta baga to four and three-quarter bushels per day. With this kind of treatment, there will be but very little difficulty in raising lambs.

But if a flock of ewes are not in such condition, and require therefore more feed and better treatment, two pounds of hay and one-quarter of a pound of grain ought to be fed daily until the rutting season is over, when the grain is withdrawn, and roots immediately given, of potatoes two or ruta baga three bushels to a hundred per day, until about lambing time, when that quantity is increased to three bushels of the former, and four and three-quarter bushels of the latter. Both flocks receive a foddering of straw or good corn-fodder, three times a week, generally at night, of which they will eat a considerable portion, and the orts serve for litter.

The three years' old wethers will go through the winter on hay, with an occasional foddering of straw, the orts of which serve them for litter. But the younger wethers require better feed, and being hard to winter, the best of hay should be given them, with some small additions of grain or roots, say one-fifth of a pound of grain, or three-quarters of a pound of potatoes, or one and a quarter pounds of ruta baga.

It being very desirable that the lambs should go through the winter in the best possible condition, much care is required, and having given them a few sheaves of oats every evening, before they were taken out of the pasture, it remains now to be determined the kind and quantity of feed they are to receive. This ought to be the best of hay, and as much of it as they will eat without cloying them. If it is well mixed with white and red clover, and was cut in good season and well cured, it should be eaten up clean. In addition to this, from a quarter to half a bushel of oats per hundred may be their daily allowance, as circumstances require.

The flock of invalids having been placed in the warmest situation, claim every care and attention, and no pains nor trouble must be spared, to carry them through the winter; so that the old ewes shall be enabled to raise a lamb each, which will pay for all the extra expense and trouble the whole has cost.

In view of the foregoing remarks, it becomes necessary to ascertain the feeding properties of grain, roots and straw, as compared with hay, to enable the farmer to make his estimate of the quantity he will require, and to calculate the probable profit or loss of raising certain crops, and feeding them to sheep.

The experiments of Mr. De Raumer, of Kaltwasser, in Silesia, in Germany, go far to establish certain facts on this subject. They are interesting to the inquiring mind, and may be considered as conclusive evidence. Mr. De Raumer is a thorough, practical and scientific farmer, and is considered high authority on agricultural subjects; his farm establishment is very extensive, and his experiments may be relied upon.

"REMARKS.

"*Potatoes* raw and cut into slices, sheep eat with continued good appetite and greediness; they ate seven pounds per head daily, with an allowance of straw. The animals remained healthy and lively, and drank one and a half quarts of water per head daily.

"*Mangold wurtzel,* sheep eat with less greediness; they ate in duration eight pounds per head daily, straw as with the potatoes, and drank scarcely one quart of water. The animals remained likewise healthy.

KINDS OF FEED.	Increase of weight in the live animal.	Produced of wool.		Produced tallow.	
		lbs.	oz.	lbs.	oz.
1000 pounds raw potatoes, with salt,	46½	6	8¾	12	5½
1000 do do without salt	44	6	8	10	14½
1000 do raw mangold wurtzel,	38	5	3½	6	5½
1000 do peas,	134½	14	11	41	6
1000 do wheat,	155	13	13½	59	9
1000 do rye, with salt,	90	13	14½	35	11½
1000 do do without salt,	83	12	10½	33	8½
1000 do oats,	146	9	12	40	8
1000 do barley,	136	11	6½	60	1
1000 do buckwheat,	120	10	4½	33	8
1000 do good hay	58	7	10½	12	14
1000 do hay, with straw, without other fodder,	31	15	8	6	11
1000 lbs. whiskey still grains or wash,	35	6	1	4	0

"*Peas,* sheep eat very eagerly, two pounds per head per day, drank two to three quarts of water in twenty-four hours, and the animals remained perfectly healthy. In an unsoaked condition, they are hard for sheep to eat and affect their teeth.

"*Wheat,* sheep eat greedily, two pounds per head daily, and disposes them to great liveliness—drank from two to three quarts of water in twenty-four hours, and remained perfectly healthy.

"*Rye,* sheep do not eat readily, and does not suit them well, as the above results in the increase of weight show—they drank from two to three quarts of water.

"*Barley,* sheep ate two and a half pounds per head daily—they thrived upon it, and drank three quarts of water in twenty-four hours.

"*Oats,* the same as barley.

"*Buckwheat,* sheep ate with great avidity and with the best results as to health and liveliness. A sheep can eat from three to four pounds, and drink from two and a half to three quarts of water in twenty-four hours.

"*Of good hay,* a sheep can consume four and a half pounds, and drink from two and a half to three quarts of water in twenty-four hours."

Mr. W. A. Kreisig, a celebrated farmer in East Prussia, considers that one pound of oil-cake meal is as nutritious as two pounds of good hay.

80 lbs. clover hay* equal to 100 lbs. meadow hay;
80 lbs. lucerne and sainfoin, equal to 100 lbs. of meadow hay;
200 lbs. sound and well cured vetches and pea vines to 100 do.
300 lbs. sound barley and oat straw, equal to 100 lbs. do.
400 lbs. sound wheat and rye straw, equal to 100 lbs. do.
100 lbs. water turnips, equal to 40 lbs. of potatoes, or 50 lbs. of mangold wurtzel.

Mr. John Philip Wagner says, in his work entitled "Contributions to the Science and Treatment of Wool and Sheep," that "200 pounds of potatoes, 266 pounds of carrots, 350 pounds of ruta baga, and 90 pounds of clover hay, lucerne and sainfoin, are each of them equal to 100 pounds of good hay."

Your committee beg leave further to cite the practice of a few of the most celebrated breeders of sheep in Germany, and firstly that of Mr. Albricht Thaer, of Moeglin, in Prussia.—Potatoes and straw constitute the main feed for his large flock of 1500 during winter He cuts them into small slices, feeding them alternately with straw. When his pastures, in the fall of the year, begin to fail, he commences feeding potatoes by scattering them in the field in such quantities as he deems sufficient, with the best effect upon their health and condition; his flock fully attests that sheep may be kept principally on roots and straw; and one of your committee, who has been familiar with sheep husbandry, both here and in Germany, confidently believes, from his knowledge on the subject, that the same practice can be profitably applied in our sheep husbandry.

Mr. Block, of Schieraw, in Silesia, Germany, one of the most intelligent and experienced breeders of sheep, keeps a flock of 500, in the following manner. He fodders six times a day.

1st fodder—208 lbs rye straw, of which they ate..		52 lbs.
2d fodder—130 lbs. oat do do do ..		97 lbs.
3d fodder—the dry sheep received 160 lbs. of pea vines, of which they ate		120 lbs.
the ewes received hay		120 lbs.
4th fodder—potatoes mixed with cut straw	750 lbs.	
rye bran,	31 lbs.	
oil cake meal,	8 lbs.	
barley meal,	33 lbs.	
		822 lbs.
5th fodder—the ewes received hay,		120 lbs.
the wethers rec'd 160 lbs. pea vines, of which they ate		120 lbs.
6th & last fodder—208 lbs. of rye and wheat straw, of which they ate		52 lbs.
Total amount consumed per day,		1651 lbs.

The flock was of superior quality, the animals large and always in excellent condition.

Count Magnis, of Eckhardsdorf, gave to 100 breeding ewes, the following per day:

1st fodder—straw and clover hacker,	69 lbs.
2d fodder—the same,	69 lbs.
3d fodder—clover hay,	100 lbs.
4th fodder—potatoes and straw hacker,	72 lbs.
5th fodder—straw,	75 lbs.
Total,	385 lbs.

The Electoral flock of Rennesdorf, the private property of the king of Saxony, consisting of 400 breeding ewes and rams, 1,000 pounds of hay in two meals, and at night a foddering of straw, was their daily portion.

Although there might be many other valuable practices of the German shepherds cited, but your committee fearing that they have already exhausted your patience, forbear to enlarge upon them, they therefore leave that subject and proceed to the consideration of the second proposition, namely, water.

---

* *Note by the Translator.*—The clover in Germany grows finer than the clover in this section of country—it resembles more the Pennsylvania clover—and yields two crops a season. It is cut when in full blow, and well cured in cocks.

All domestic animals require water in proportion to the quantity of dry provender they consume; and sheep require particular attention in this respect, as well as some care in regulating the quantity, according to circumstances. Warm springs are always to be preferred, though individuals are frequently to be seen eating snow, which may generally be attributed to fever; and is by no means to be considered a substitute for water.

It is desirable that the flock should be able to drink without wetting their feet or wading into mud, both which are not only very injurious by creating disease in the foot, but deter sheep from drinking as often as inclination prompts.

Protection against the inclemencies of the season is the third consideration in the "feeding and management of sheep in winter." It is almost as necessary to their health and prosperity as food itself, and for this reason, comfortable shelters should be built for them; they not only do much better, but it is a great saving of time, fodder and manure. It will be found that ten tons of hay, fed to sheep that have warm shelter, will go further than twelve tons fed out to them from a stack, and when they have no other protection from the inclemencies of the weather than the side of a stack or fence. Such stables, if properly constructed, will at least pay from 15 to 25 per cent interest annually. This alone should prompt the owner of a flock to provide comfortable lodging places for them. But "*a merciful man is merciful to his beast.*"

Each full grown sheep requires six square feet of room, including racks. The stable should be eight feet high, with windows in the upper part, that may be closed as circumstances require. The floor over head ought to be made tight, that nothing can fall through. They must be well littered, as it will add much to the health and comfort of the animal. If they are not well littered, the dung accumulates, and creates an offensive smell; sheep are then very loth to enter them. It is but too often the case, that when farmers *do* shelter their sheep, the stables contain a mass of dung, so offensive that the flock would not enter them, and if forced in and confined there, would prove injurious; and hence the prejudice, "that housing sheep is injurious to their health."

Your committee regret, that circumstances over which they had no control, prevented their coming together sufficiently early to do justice to the importance of the subject committed to them. FRANCIS ROTCH, *Chairman.*

Report of the Committee on Root Culture.

The committee appointed at the last meeting of the Society, to "report on the best vegetable or root crops for feeding cattle, and the best means of cultivating the same," report as follows:—

The culture of roots, as farm crops, for feeding and fattening domestic animals, is of such recent introduction, and so limited, among us,—and the few experiments that have been made, to ascertain the relative value of these roots, have been so loosely managed, that the committee do not possess the data that they could desire, to make a satisfactory report, adapted exactly to our practice. But they are nevertheless satisfied, from the numerous experiments which have been made in Europe, in a climate very similar to our own, and from the partial ones which have been made among us, that the culture of roots is destined to effect here, what it has effected elsewhere—a great and salutary change in husbandry; —not only as furnishing the easiest and cheapest means of feeding and fattening domestic animals, but as an important source of fertility to the farm,—and of securing the main point —ultimate profit—to the owner or cultivator.

Under these strong impressions of the advantages of encouraging and extending root culture, your committee proceed, with the limited means at their command, to fulfil the duties assigned to them by the Society.

The Highland Agricultural Society of Scotland have recently awarded liberal premiums for experiments in fattening neat cattle,—*first*, upon different kinds of roots, as the potato, turnip and mangold wurtzel;—*second*, upon raw and cooked food; and *third*, upon roots entirely, and a mixture of roots, grain, pulse and oil-cake. These experiments have been made with a view of accurately ascertaining the comparative value of each kind of root and other food, and the economy of each mode of feeding it. The experiments have been numerous. They have been made upon ten to thirty head of cattle at a time; and they have been continued from three to six months. The animals were weighed or measured at the time of starting the experiment, at the close of it, and generally at intermediate periods, particularly when the food was varied; and the quantity of roots and other food given was accurately noted,—so that the result has indicated the relative value of each kind of food in the fattening process, and the best mode of feeding it. The committee proceed to state, in a summary way, the results of some of these experiments.

1. *The relative value of different roots.*

Mr. Howden, with a view to the experiment, set apart the product of two acres of mangold wurtzel, amounting to fifty tons, five acres of Swedish turnips, being 140 tons, and two acres of potatoes, weighing 29 tons 4 cwt. The experiment was made with 21 head of cattle, which received, in addition to the roots, a few distillers grains and a little straw. The following table shows the roots appropriated to each lot, and the monthly increase of the animals in girth. The abstract is made from the prize essays of the society, which cannot now be referred to; but the impression is, that in all the experiments which we quote, the roots fed to each lot was precisely the same in weight. Lot No. 1 was fed from the product of one acre of potatoes, one acre of mangold wurtzel, and one acre of Swedish turnips; No. 2 from one acre of potatoes and two acres of Swedish turnips; and No. 3 from one acre of mangold wurtzel and two acres of Swedish turnips.

Date.	Lot No 1	Lot No. 2	Lot No. 3
1831, Nov. 30,.	35ft. 8 inches,	35ft. 9 inches,	35ft. 8 inches,
Dec. 30,.	36 " 6 "	36 " 7 "	36 " 6 "
1832, Jan. 30,..	38 " 2 "	38 " 4 "	38 " 2 "
March 1,	39 " 7 "	39 " 8 "	39 " 6 "
" 30,	40 " 8 "	40 "10 "	40 " 6 "
April 30,	41 " 4 "	41 " 7 "	41 " 3 "

Twenty-eight tons of mangold wurzel and Swedish turnips were withdrawn to feed other stock.

On the 30th January Mr. Howden took a pair of cattle out of each lot, and fed No. 1 with potatoes and water, No. 2 with Swedish turnips, and No. 3 with mangold wurtzel. The following shows their relative increase in three months.

Date.	Lot 1 Potatoes.	Lot 2 Swed. turnips.	Lot 3 Man. wurtzel.
1832, Jan. 30,..	10ft. 8 inches,	10ft. 5 inches,	10ft. 4 inches,
April 30,.	11 " 6 "	11 " 3 "	11 " 2 "

When the cattle were sold, the purchasers agreed that the lot fed on Swedish turnips were from 7s. to 10s. ($1.54 to $2.22) a head better than the other lots. The average advance upon the original value of each was £6.12, and the cost of the grains being deducted, there remained £120 ($532.-80) in return for the eight acres of produce consumed, or $66.60 for each acre.

From the above statement it would seem there is no great difference in the fattening properties of the three kinds of roots; and that so far as measure or weight is concerned, it matters little which are employed in feeding. We will note here for future reference, the product per acre, of each kind of roots, upon Mr. Howden's ground, adding the product in bushels of 56 lbs.

The potatoes gave 12 tons 4 cwt. equal to 483 bushels.
The mangold wurtzel 25 tons " 1,000 "
The ruta baga 28 tons " 1,120 "

2. *The comparative economy of feeding raw or prepared food.*

In 1833 the society offered a premium of 30 sovereigns for the best report, founded on actual experiment made for that purpose, on a number of oxen or heifers, not fewer than six, the animals to be of the same breed, age and sex, and the term of feeding not less than three months. Several reports were received and published in 1834. From these we abstract the following:

Mr. Walker made his experiment with six two year old heifers, and four two year old steers. Each parcel was divided into two lots, and fed on like food, except that one half received their food raw, and the other half in a steamed or cooked state. The food consisted of Swedish turnips, potatoes and crushed beans, with a little salt and straw. At the end of three months, it was found that the three heifers fed on steamed food had gained 48½ stone, or 679 lbs. and the three heifers fed upon raw food had gained 45½ stone; but the quantity consumed by the first lot exceeded that of the latter.

Cost of feeding on steamed food,........... £14 1 3
" on raw food, ... 10 8 7½

The first cost more than the last £3 14 8½

Deducting the first cost, and the price of fattening from the price paid by the butcher, there remained a profit on the three heifers fed with steamed food, of 9s; while the profit on the three fattened with raw food amounted to £3 10s 6d. By a like estimate, the loss on the steers fed with steamed food was 3s. 8d. and the profit on those fed with raw food 10s. 6.

Andrew Howden made a like experiment with 18 cattle, in six lots. Their increase, and expense of keeping for three months, from the 20th March to the 20th June, were as follows:

	Incr. in lbs.	*Expense.*
Three heifers on raw turnips,.......	392	£6 18 0
" on steamed turnips,.......	532	8 18 0
" on raw potatoes,.......	600	10 7 0
" on steamed potatoes,.......	572	10 7 0
Three steers on raw potatoes and corn,	722	9 4 0
" on boiled potatoes and corn,	639	9 5 0

John Baswell fed ten horned cattle. The expense of keeping the five cattle on raw food was £32 2. 1, while that of the cattle on prepared food was £34 5 10. On being slaughtered the two lots appeared to be very similar, but the particular weight is not mentioned.

3. *Relative economy of feeding with turnips alone, or with turnips and other more expensive food.*

Robert Stevenson was the successful competitor for the society's premium. He took 18 oxen; their live weight was ascertained at the beginning, at the end, and at intermediate periods of the experiment, which continued 119 days. The cattle were divided into three lots of six beasts each, and a correct account was kept of the weight of food consumed by each lot. Lot 1, was allowed lintseed cake, bruised beans, and bruised oats, in addition to turnips, and during the last 24 days of the experiment, 20 lbs. of potatoes were given per day to each. Lot 2, received the same allowance except the lintseed cake, and half the potatoes. And lot 3, was fed upon turnips alone. The cost of the keep of each animal, during the 119 days, was as follows:

Total cost of feeding one beast of lot 1,.......£5 2 7
do do do of lot 2,....... 3 17 0
do do do of lot 3,....... 1 18 7½

The improvement in live weight was as follows,

First lot increased in weight........ 108 stone.
Second do do .... 101 "
Third do do .... 49 "

Abstracting the cost of feeding from the value of the increased weight, the loss and profit would stand as below:

Loss on feeding lot 1, ...£3 15 8¾
Profit on feeding lot 2, ... 1 19 3½
Profit on feeding lot 3, ... 2 11 1

"Thus, when turnips alone were used, a profit of twenty-two per cent was realized; where beans and oats were used along with the turnips, the profit was diminished to eight and a half per cent; but when still more expensive food was tried, that is, grain and lintseed cake, along with turnips and potatoes, a loss was sustained of no less than 12 3.16 per cent."

Lot 1, were the largest oxen. They were fed each with 132 lbs per day of Swedish turnips; lot 2, were fed each with 120 lbs. of the same per day; and lot 3, being the smallest, received but 115 lbs. per day, and for twenty-four days but ninety two pounds.

Lot 1, cost 4.484 pence for every pound of increased live wt.
Lot 2, " 3.92 " " "
Lot 3, " 3.39 " " "

The turnips were estimated at four pence per cwt; the potatoes at 1s. 6d. per cwt.; oats and beans at 3s. 6d. per bushel, and lintseed cake at three-fourths of a penny per pound.

"In conclusion " says Mr. Stevenson," on this part of the subject, " we give it as our opinion, that whoever feeds cattle on *turnips alone*, will have no reason, on the score of profit, to regret their not having employed more expensive auxiliaries to hasten the fattening process."

It would seem pretty evident, from the foregoing experiments, that ruta baga and mangold wurtzel are the best root crops for feeding cattle. The profit of cultivating and feeding these roots will be more manifest, if we compare their acreable product with that of hay, potatoes, and the coarse grains which we feed to fattening animals. To enable the committee to make this comparison, they assume the following as the average products of crops, and attach to each of these an estimate of their marketable value. Both the product and the prices will greatly vary; but those assumed are deemed sufficiently correct for comparison.

An acre of grass,	2 tons at $10,.			....	$20 00
do corn,	40 bushels at 75 cts.			......	30 00
do oats,	30	do	at 37½ cts.	.....	11 20
do buckwheat,	30	do	at 50 cts.	......	15 00
do potatoes,	150	do	at 25 cts.	......	37 50
do ruta baga,	600	do	at 25 cts.	......	150 00
do man. wurtzel,	600	do	at 25 cts.	......	150 00

Estimating the cost of the roots, in labor, at twenty dollars an acre more than that of the hay, oats and buckwheat, it still leaves a great disparity in the profits; and considering the cost of culture equal to that of Indian corn, there is a manifest advantage in the turnips and mangold wurtzel over the corn crop, as a material for cattle food. Good beef cannot be made on hay alone, in winter: and those who do not feed roots, must resort to some more expensive food, as the meal of Indian corn, oats, buckwheat, &c. The turnips and mangold wurtzel, on the contrary, with the aid of perhaps a little straw, will serve of themselves to feed and fatten animals.

In this matter the chairman can speak from experience. He purchased four oxen a little before Christmas, and kept them till some time in April; after a short time, they ate each two bushels a day of ruta baga;—they would eat very little else, though laid before them, not even lintseed cake. They made good beef, and afforded a handsome profit on the turnips consumed.

If we now assume that an ox will require a quarter of a hundred of hay per diem to keep him in good condition, and that it will require an addition of four quarts of corn meal, or eight quarts of crushed oats or buckwheat, per diem, to fatten him; and if we consider 112 pounds or two bushels of roots equivalent to a ration of hay and grain, then the several crops will feed an animal as below.

One acre of grass, and half an acre of corn will feed 160 days.
One and a half acres of mangold wurtzel, or Swedish turnips will feed......................... 450 days.
One acre of grass, and one acre of oats or buckwheat will feed .... 160 days.
Two acres of Swedish turnips or mangold wurzel will feed .... 600 days.
One acre of potatoes will feed .... 75 days.
One acre of Swedish turnips or mangold wurtzel will feed .... 300 days.

Making very liberal allowance for the difference in the expense of raising these crops, and for any error the committee may have made in fixing the daily rations, or in the acreable produce of each, they think that no doubt can for a moment be entertained, that the Swedish turnip and the mangold wurtzel are decidedly the best crops that can be raised for feeding and fattening cattle.

The committee have no doubt that the sugar beet and the carrot offer advantages nearly or quite equal to the roots above recommended. Their product and nutrient properties are very similar, and the expense of culture is not very dissimilar. The sugar beet is probably richer in nutriment than the mangold wurtzel, though its product is ordinarily less. The carrot may require more labor in the culture; but it is superior as food, particularly for horses.

Arthur Young highly extols the carrot. Upon the product of three acres of this root, he assures us, he kept for more than five months, twenty work horses, four bullocks, and six milch cows; nor did the animals, during that period, he adds, taste any food, except a little hay. Our enterprising fellow citizen, Col. Meacham, of Oswego, has gone largely into the culture of carrots, as cattle feed, as well as many of his neighbors; and they speak highly of the profits of the culture.

Some highly satisfactory experiments have also been made among us, on a limited scale, in cultivating and feeding the sugar beet. There seems to be little doubt, from the high state of perfection and of profit, which the business has arrived at in France and Germany, that the culture of this beet will soon be extensively gone into in this country, for the purpose of making sugar; and if so, the residium of the beet will form an important item in the material for fattening cattle.

There are other advantages resulting from root culture which should not be overlooked. It tends greatly to increase the quantity of manure on the farm, to meliorate the texture of the soil, and to furnish excellent alternating crops in convertible husbandry. In selecting for culture, the farmer should choose the roots that are best adapted to his soil. The turnips prefer a dry sandy soil; the beet a clay loam.

As to the best means of cultivating these crops, the committee summarily remark, that the product and profit will materially depend upon the following contingencies: viz, that the soil be dry; that it be rich; that it be deeply worked; that it be well pulverized; and that the after culture be well managed. The implements necessary to cultivate them advantageously, in addition to the plough and harrow, are the drill-barrow and cultivator. The season for sowing the beet is from 10th to the 20th May;—of sowing the Swedish turnip, from the 10th to the 25th June. The drill or row culture is decidedly the best. A detail of the whole process of culture would occupy too much space for this report, and is unnecessary, as these processes are already understood by many, and have been minutely described in the agricultural periodicals of the day. The committee will merely recommend in conclusion, that the roots be always cut, previously to being fed to cattle, for which machines may be procured, at a moderate charge, which will cut a bushel in one to three minutes. If cut, the roots are eaten entirely; if not cut, a portion is apt to be rejected and wasted.

The chairman has received a communication from Col. Meacham, stating his mode of cultivating the carrot, the product, and manner of using the crop. He cultivates them in drills, from 20 to 24 inches apart—he gets one thousand bushels an acre, at an expense of $25 to $30; he kept six work horses on them from Nov. 1836 to June 1837, without grain, and they remained in good plight, and performed as well as he ever had horses perform;—and he thinks they are worth double as much for stock as ruta baga.

Upon the subject of the carrot culture, which is perhaps less understood among us than that of the beet and turnip, the committee will add, that this root thrives best in a sandy loam, light, moist, but not wet, and of great depth; in which the plough, going to the beam, brings to the surface nothing that is not fit for vegetation. The ground should be ploughed immediately preceding the sowing. In Suffolk, Eng. they sow 8 lbs. seed, broadcast, to the acre; and the crop is from 400 to 500 bushels. To horses they are considered superior to any other food. Two bushels of carrots and one of chaff is the per diem allowance to a horse; or 7 bushels of carrots and one bushel of oats is the allowance for a week. They are also profitably fed to all other farm stock. They are raised in Suffolk without dung, at an expense of 9d. (16 cents) per bushel. The yield of the carrot is often 700 to 1000 bushels the acre. The crop is gathered by making a deep furrow near to the drill; when a man seizes, draws the top to the furrow, and pulls them up with great facility.

Another root, the parsnip, is deserving of notice, though its partial culture, hitherto, will hardly entitle it to be classed among field crops. It is believed to be the most nutritious root of any that have been named; is as easy cultivated as the carrot or the beet: and has this advantage over all the others, that its value is not impaired by frost.

From the preceding views, the committee do not hesitate to recommend the extention of root culture, as the most ready means of keeping up the fertility of our farms, and of increasing the profits of their cultivation. J. BUEL, *Ch'n.*

Report of the Committee on Swine.

Until recently, very little attention has been paid to the breeds of our farm stock; and pigs being considered an inferior species of domestic animals, have been the last to engage the attention of the farmer; and even at the present day in many districts of our country, the old unprofitable kinds of this animal continue to prevail. Indeed, systematic breeding with a view to improve the form and value of the animal, may be said to have hardly commenced among us, the improvements which are perceptible, being rather the fruits of European than American skill.

A common error in this country, has been to regard more the size of the animal, than its symmetry or good points—to estimate a breed according to the great weight which it could be made to attain—rather than the profit with which it would be fitted to the hands of the butcher—the most material point to the farmer. But experience is teaching us a new lesson on this head. Butchers now judge of an animal, not according to its gross weight, but according to the good points, or most valuable meat, which it carries. Breeders have learned to prefer those which, with a given quantity of food, will lay on the most meat. And the consumer has learned, too, that meat that shows the most solid fat, is neither the most healthy, the most savory, nor the most economical. It is the due admixture of fat and lean, or the prevalence of what is termed *fat-lean*—such as is seen in the Devonshire ox and the South Down sheep—that gives the greatest value to the butcher's meat.

It was lately remarked by an eminent breeder of England, Mr. Gray, at an agricultural dinner, that he could feed on an acre of land, a greater number of pounds of mutton, in carcasses from 18 to 20 lbs. per quarter than in carcasses from 28 to 30 lbs. per quarter, and that a quarter of mutton from a sheep of 18 to 20 lbs. weight per qr. is worth more in proportion than from a sheep of 30 lbs. per quarter; and that, consequently, the advantage is on the side of the smaller carcasses. And he assigned this, among other reasons, that in case of drought or scarcity, a small animal can collect as much food as a larger one, and having a smaller carcass it derives more advantage from it; that whilst the larger is losing in condition, the smaller one, if not improving, is remaining stationary; and when the period arrives at which an abundance of food can be obtained, it almost immediately reassumes its position, and is fit to go to market sooner than the larger animal.

These remarks are found to hold good in regard to swine, as well as sheep. The same quantum of food that will give 600 pounds to hogs of a very large breed, will fatten two hogs of 300 pounds each: and the meat of the latter, though not so fat, will be of the better quality. This, and other considerations, have given to what is termed the Berkshires, a decided superiority both in England and America, over most other breeds.

The history of the introduction of this breed among us, was stated in the report upon swine, made at the last meeting of this society. Since that time, the demand for this breed of pigs, from almost every state in the Union, has greatly increased, and prices, in some cases, have almost exceeded credulity. Two hundred and fifty, three hundred, and even five hundred dollars a pair, have been paid for them. Nor have they been found deficient in weight, when they have had time to mature their growth. They have been fattened to weigh five, six, and seven hundred pounds; and one was brought to this market last week, from Fulton county, eighteen months old, purchased of Judge Buel a little more than one year ago, which weighed, when dressed, 633 lbs. the carcass of which sold in the market at about $56.

But it is not the great weight which this breed of hogs are brought to, that gives them their great intrinsic value. They are docile, quiet, come to early maturity, have but little offal, give a large and excellent ham, one of the most valuable parts, sweet, sound and high flavored pork, and is believed, make as great, if not greater returns for the food consumed, than any other breed amongst us.

It is a matter of congratulation to the admirer of this breed of hogs, that Mr. Lossing of this city, has recently imported three animals of this breed, carefully selected by Mr. Hawes, in England. This, it is hoped, will prevent the necessity of breeding in-and-in, and thus preserve to us the breed in its purity.

In corroboration of the high opinion entertained of this breed of hogs, I will state, that Col. Williams, a spirited and wealthy gentleman, residing on Long-Island, desirous of procuring a superior breed of hogs, wrote to his friend and agent at Liverpool, to procure for him, *without regard to price, six pigs of the best breed in England*, and to take time and satisfy himself before purchasing. After diligent inquiry, his friend finally settled on the Berkshire, as being considered, taking all things into view, the best and most approved breed, and purchased seven, four males and three females, being the entire litter, (the owner refusing to sell a part,) and forwarding them to New-York, where they arrived in October last. One of the male pigs will be forwarded to the chairman of this committee in the spring, which will go still further to keep the breed from degenerating.

There are other good breeds of hogs in some sections of the country, each of which have their advocates and admirers, such as the Bedford or Woburn, Mackey, Leicesters, Mocho, China, Byfield and Grass-breed, as they are termed.

Much loss has been sustained by our farmers, in not keeping up the purity of blood, when possessed: the importance of which has been too little regarded, and before they were aware of it, the good qualities were lost, either by breeding in-and-in, or by crossing with inferior animals.

As regards the choice of hogs for breeding, it is recommended that the male should be small headed, deep and broad in the chest, the chine rather arched, the ribs and barrel well rounded. and the hams falling full down nearly to the hock. He should also be more compact in his form, and rather smaller than the female, for if she be coarse, her progeny will be improved in form and flesh by the cross, and the more roomy she is, the better chance will she afford of producing a large and healthy litter. Respecting her make, no other observation need be made than to choose her of a deep and capacious body with a good appearance, and belonging to as good a race as can be found.

The boar should be well fed, and when young, used sparingly. The sow should also be kept in good condition, so as to support her offspring, but should not be made too fat; for if in very high order she will probably bring but a weak and indifferent litter of pigs. She should not be allowed to farrow in the winter, as the young are then extremely tender, and of all animals the least able to endure cold, and thrive with great difficulty. The months of March and the first of April for the spring, and the months of August and September, for the fall litters, are therefore to be preferred for farrowing.

When breeders possess a good kind of stock, they are too apt to follow it up, by breeding what is termed "in-and-in" with the same family; a practice which is well known cannot be successfully persevered in, for they will become bad feeders, grow delicate, fall off in size, and almost entirely give up breeding; and should they casually have a litter, the pigs will be small, weak and, and die almost as soon as they are born.

It not unfrequently happens, that a young sow will devour her young; she should, therefore, be carefully watched, and well fed, when about to farrow: which may be known by her carrying straw in her mouth, about to form her bed. It is a good precaution to sponge the backs of the pigs immediately after they are born, with a strong infusion of aloes, in lukewarm water, as its bitter taste will prevent her from destroying them, care should also be taken before farrowing to separate her from other hogs. She should have a dry and warm place, and be provided with a good supply of straw cut short, to prevent the pigs from getting entangled, in which case she is apt to lay on and kill them. To protect the pigs, an open frame or strong rail on each side of her, elevated a few inches from the ground, under which the pigs may run, has been recommended. Eight or ten days after farrowing, the sow may be allowed to leave her stye for a short time every day, and when the pigs acquire a little strength, they may accompany her. A grass field is the best place, for the herbage improves the sow's milk; the pigs grow faster as well as more healthy, and the stye is rendered more sweet by their absence. If the brood be numerous, they should be lessened, in order to relieve the sow, to eight or at most nine: though from ten to thirteen have been brought up in perfect order, without any apparent injury to the mother. In such cases, however, she should be a strong and healthy animal, as well as supplied with an abundance of the most nutritious food. During the whole period of her nursing, the offals of the kitchen or dairy wash, with ship stuffs, ground oats, barley, buckwheat or corn, mixed and given lukewarm, morning and evening, and in the middle of the day, boiled potatoes, beets or carrots, with a little Indian meal or peas and barley ground and mixed, or something equally nutritious.

The young pigs, even while sucklers, should not be left wholly to the nourishment offered by the sow, but should be furnished, two or three times a day, with skim-milk, or buttermilk-whey or pot liquor, made lukewarm, and having a little meal, shorts and boiled roots, mixed up with it: or if this be thought too troublesome, skim-milk, with a small quantity of meal may be left constantly for them, in a part of the stye to which the sow cannot have access. In six or seven weeks, they will generally weigh from thirty to thirty-five pounds and be strong enough to wean. After weaning they should not only be kept dry and clean, but regularly fed.

The importance of the value of swine, with regard to the consuming of the refuse or coarse grain of the farm, and production of manure, is too well known to the farmer to require further notice.

Pigs that come in March, and are intended to be killed in December, should be well fed with the wash of the kitchen and dairy, from the time of weaning, and have a run in good clover where there is plenty of water, and as soon as peas will answer, a small quantity added to their feed daily, and the quantity increased as they increase in size; as feeding and fattening hogs exclusively on corn, at the present high prices, it is evident to every one, would be a losing and ruinous concern. It is therefore recommended, that as soon as the harvesting of potatoes commences, the hogs should be confined and fed with boiled or steamed potatoes, with a few pumpkins, beets or carrots; and peas, oats and buckwheat, ground together, should be well mixed, when hot, and fed lukewarm, regularly three times per day. Great care should be taken not to cloy their appetites, by feeding more than they will eat at each time, and as they advance, it is recommended to feed them a little at a time, several times in the day. To keep them easy and quiet, much depends on regularity, for they keep much better time than many are aware of.

To harden and give solidity to their flesh, about two or three weeks previous to their slaughtering, they should be plentifully fed with corn and pure water, but it would be more economical to have the corn reduced to meal, and if convenient made into mush or pudding, adding a little salt by way of relish. A small quantity of fine charcoal thrown into their pens occasionally, and a small quantity of sulphur, mixed with the food, will add much to their health.

It has been ascertained that one bushel of grain, ground and cooked, will go nearly as far as two, in its whole state. The above remarks will apply equally well to grown hogs.

March pigs, well fattened, weighing from 200 to 250 pounds and killed in December, will command in this market the highest price; but for consumption on the farm, an older and larger hog is recommended, say from 300 to 400 pounds.

Hogs treated as above, if of a good breed, will require from six to eight weeks to fatten them sufficiently for slaughtering. C. N. BEMENT, *Chairman.*

Report on Grasses and Grass Lands.

The committee on laying down grass lands, &c. report:

In the consideration of this subject, but two distinct propositions submit themselves to the reflection of the committee, and first: Our soils in the northern states may be ranged, for the purposes of this essay, into two classes: the tenacious, consisting of clayey, loamy and vegetable: and the silicious or sandy. These are sufficiently well known to every farmer, without analyzation, and the committee believe that the long practical experience and observation of their several properties, need only to be here confirmed and reiterated.—The first division of these soils may be termed "natural grass lands;" the second requires the grasses to be frequently cultivated by rotation with other crops; and for the present purpose, may be termed "artificial" soils for grasses.

In the management of the first, the committee feel warranted in the assertion, (and for the truth of this, they appeal to the innumerable instances afforded in all parts of the northern states, when large and productive tracts of meadow and pastures, have been in uninterrupted grass culture for more than half a century,) that so far as has yet been tried, lands may be kept in grass culture for such time as "the memory of man runneth not to the contrary." It is true that these soils, more than others, will not bear continual cropping without occasional nourishment, with impunity; but when once well seeded, by the application of various manures, among which that of the barn yard is the best, and the absence of close after-feeding, they will yield grass, in common parlance, "almost forever."

In many sections of our country, when the vegetable loam preponderates upon a clayey, or a hard-pan subsoil, the ploughing up of meadows and pasture lands for many years is almost destructive to their future production of grass, and it is only by long and regular applications of mixed and rich manures, that they can be brought back to their primitive luxuriance. In proof of this remark, your committee need only refer to some of the most celebrated and productive grazing districts of the state, where the staple grasses of our country have been *always* successfully cultivated. In frequent instances, perhaps in a large majority of cases, lands of this description, which have been cleared within the last fifty years, and now occupied as pasture and meadow, have *never* been ploughed, but remain in the same uneven condition of surface, as they were left, when the harrow followed the first grain and grass seed which were deposited in them after clearing. Great reluctance is usually manifested in disturbing these fields, although somewhat inconvenient to the mower, so well satisfied are their proprietors with their annual crops, as to prefer the old adage, and "let well enough alone."—Your committee have witnessed instances of this description of soils thirty years in grass, and but slightly manured, and under very ordinary cultivation, producing in a common season, two to three tons of the finest hay per acre. Such, however, are extraordinary cases in favorable positions. An ordinary crop may be one to two tons per acre, according to the care and attention of the farmer.

It is true that these lands may become exhausted, and the grass "run out," as the term goes, by bad husbandry and neglect; but the application of yard manures, of new grass seeds and the harrow, will in nearly all instances, restore them to their wonted luxuriance. It need hardly here be stated, that irrigation, draining and other artificial stimulants may be important acquisitions to the productiveness of the meadow and the pasture, but as these always suggest themselves to the judgment and good sense of the cultivator, they do not necessarily come within the province of this discussion. The quantity of seed sown to the acre for either pasture or meadow, should not be less than half a bushel; the kind or variety to depend somewhat upon the soil and its situation. For mowing, the red clover, timothy and red top are the best and most desirable. For pastures, the same, with the addition of white clover and blue or June grass, which are almost everywhere indigenous to the soil, and are among the richest and most nutritious of all our grasses. In fine, the simplest methods compatible with the established rules of good husbandry, your committee believe, with such soils, are the best for their profitable and perpetual cultivation.

In the discussion of the second proposition of the subject, viz. the cultivation of grasses on the lighter soils, your committee will remark, that much will necessarily be left to the judgment of the cultivator, in the time that his lands are to be kept in grass, and his own necessities or requirements of his soil. As a general rule, if the raising of grass be an object, so long as the lands produce well, either from their natural fertility, or by the application of artificial stimulants, they should not be disturbed; but when the object is a regular rotation, with a strict regard to profit, two to four years is sufficient for the benefit of the land, and as long as such soils will usually yield a grass crop to profit. It is better that the soils be properly prepared, by previous grain or root crops and abundant manuring, harrowing and rolling, for the reception of grass seeds, and that the manures of the farm, save, perhaps, lime, ashes and plaster, be withheld for the use of the current ploughed crops, than to expend them upon the grasses; yet much must depend upon the local position of the ground, the climate, and the dry or moist condition of the soil.

The descriptions of grasses best fitted for these soils are, so far as our experience has yet tested, the red clover and timothy. They are strong, hardy and rich in their properties, universally known and cultivated, and have, in competition with all rival experiments, maintained their reputation and superiority. The proportions of seed to be distributed on the soil, may vary with the requirements of the cultivator, whether for hay or for pasture; but may range from one to two-thirds of either variety; but in no case for *thorough* seeding, should the combined quantity be less than half a bushel to three pecks per acre. The great fault with our farmers is, to not half seed their grass lands, the usual allowance being less than half the quantity recommended. The time and manner of seeding, your committee unhesitatingly recommend, as the earliest spring, on a light loam; or if that be wanting, while the ground is yet unsettled, on a crop of winter grain. If this mode be not practicable, the best other plan would be either by sowing with spring grains, or seeding in the summer, with buckwheat or turnips as the occasion may demand.

The ploughing into the soil, of an occasional grass crop for its renovation, in the absence of stimulating manures, cannot be too highly recommended in the lighter soils; and for succeeding crops of almost any description, this process is highly advantageous, and may, without hesitation, be always recommended.

As the discussion of this subject at greater length, would lead your committee into minute details, although highly profitable in its results, yet not required by their duties for this occasion, they beg leave to close their communication with the following suggestion to all who would cultivate grasses:

Read attentively, and follow the experimental and practical rules laid down in the agricultural papers of the day, and no intelligent farmer need be at a loss to understand how to best cultivate his lands with grasses.

L. F. ALLEN, *Chairman.*

EXTRACTS.

[*From the Journal of the American Silk Society.*]

Address to the People of the United States.

Fellow Citizens—A convention of the friends of the silk culture assembled in Baltimore on the 11th ult. and remained in session for three days. Delegates were present from eleven states, and the District of Columbia, amounting in number to nearly three hundred; and, we believe, that for intelligence and respectability, this assembly would not suffer in comparison, with any body, of equal numbers, which any of the great interests of our country have brought together. Among those assembled were a number who have been practically engaged either in the culture or the manufacture of silk, and they exhibited various specimens of this beautiful and valuable article, which certainly gave fair promise of success to those who shall engage in the business. This convention, in the course of its transactions, appointed the undersigned to address you on the importance of the silk culture; and we now ask your attention while we endeavor to show that you will promote both the interests of the country, and your own individual prosperity, by giving this business a fair trial.

That it is desirable the United States should become a silk growing country, provided it can be done with a fair profit to those engaged in the business, is so evident that little need be said upon the subject. The consumption of this article has been rapidly increasing, particularly within the last few years. In 1821, the amount of the silks imported, as ascertained from the custom-house returns, was not quite $4,000,000. In 1825, the amount had arisen to nearly $10,500,000; and in 1837 to over $20,000,000. It should be borne in mind too, that we import other articles either of necessity or luxury, nearly or quite equivalent in cost to the value of all our exports; and the consequence is, that we must either run in debt for the principal part of the silks we use, or be subject to a constant drain of the precious metals. A system like this cannot be long continued consistently with the prosperity of the country. We must curtail our imports of this article, or we must produce the raw material ourselves, and export it to pay for such of the silk fabrics as we cannot with profit manufacture for ourselves.

We might extend our observations upon this branch of the subject, did we not believe that no further argument is necessary to satisfy you, that we ought to become a silk growing country provided the business will yield a fair profit to those who undertake it. Let us proceed then to this inquiry.

In the first place it may be stated that the climate of our country, and much of the soil, are such that the silk we make is not excelled, either in beauty or strength by that of any country in the world. For the truth of this fact we may appeal to the testimony of every foreigner, capable of judging, who has had an opportunity of testing our silk. Shortly prior to the revolutionary war, no less than 10,000 lbs. of raw silk were sent from the colony of Georgia to London, and its quality was such that it commanded from two to three shilling sterling per pound, more than that of any other country. We are not aware that any considerable quantity has been sent to Europe from states farther north, but European manufacturers have frequently examined it, and they have uniformly given it the character stated above. We can produce then excellent silk, in the various parts of our country, and to any desirable amount. But we are frequently met with the argument, that although our soil and climate are both very favorable to this culture, still labor is so high that we cannot compete with the silk growing countries of Europe and Asia, where the price of labor is extremely low.

Many of you will no doubt recollect that prior to the war 1812, although we were growing large amounts of cotton, we received all our more common and substantial muslins from India. During the war, when our commerce was greatly reduced and the prices of all imported articles became very high, cotton manufactories were commenced in some of the eastern states, and helped to supply the deficiency. When the times of peace again arrived and commerce revived, it was very generally predicted that those manufacturing establishments must be broken up, as the principal articles they then made were such as to bring them into direct competition with those countries where the price of labor was at its lowest point. Was this prediction verified? Far from it. Those manufactories have been greatly extended, and they now give us muslins for less than half the price we formerly paid for those of India, and of a quality greatly superior. In fact we now export such muslins to India, and sell them at a good profit. The high price of labor, in this case, then, has not prevented a successful competition with those countries where the wages are such as scarcely to afford the most meagre subsistence to the population engaged in it. Why then should the high price of labor prevent our raising silk to a good profit? The fact is, and it may be applied to all cases, that those countries where labor is very low, business is carried on much more sluggishly than where it is high, and their implements are more rude and less adapted to the purpose; so that the same amount expended will not produce more in the former case than in the latter.

But we need not proceed further with general arguments, to prove that the silk culture will be a profitable branch of national industry; facts were elicited during the sittings of the convention, which are more to the purpose than any arguments we could use. The Rev. D. V. McLean, of Freehold, New-Jersey, stated that, in order to try what amount of silk could be made from a given portion of ground, and that too by a person who had no practical knowledge of the business, be planted a small lot of known dimensions, with morus multicaulis, in the spring of the past year, and that he made during the summer, from this lot, at the rate of 510 lbs. of cocoons or 51 lbs. of raw silk per acre. He further stated that, for want of a sufficiency of the silk worms' eggs, he did not feed nearly so large a number as his foliage would have supported. But suppose we take this amount as the average per acre, and it is certainly not too high, and we shall presently find that the business will yield a large profit. The value of the raw silk is not less than $5 per pound, which will give us $255 as the gross produce per acre. The gentleman above named did not keep any account of the expense of collecting the leaves, attending to the worms, &c; but, a Mr. Smith, a very respectable farmer of Amherst, Massachusetts, who has been for several years engaged in the culture, stated that he knew from actual experiments, that when he paid the full price for labor it did not cost him more than $2 per pound for the raw silk he obtained. Other gentlemen present, who had considerable experience in the business, corroborated his statement—suppose, however, that in order to be perfectly safe in our estimate, we add 25 per cent. to this amount making the expense of producing the pound of raw silk $2.50 or $127.50 for the 51 lbs. and we have a nett profit of $127.50 per acre. Permit us now to ask you, what branch of your usual business yields a profit any thing like this?

We see then that if the silk culture is undertaken by the farmer as an exclusive business, it will yield him a rich return, even when he has to pay the full price for all the labor employed. But if ever the United States shall become extensively engaged in this branch of industry, and that it will eventually become so engaged we have not the shadow of a doubt, by far the greater portion of the article will be produced by farmers or planters, who are at the same time raising their ordinary crops. Most of the labor can be as well, and as expeditiously, performed by children of from nine to twelve years of age as by robust men; and thus a large proportion of our population, who are consumers but produce nothing, may be most profitably employed during a portion of the year. Every farmer who has a family of children about him, by planting a small portion of his ground with morus multicaulis, may make from 50 to 200 lbs. of raw silk per year, with very little interruption to his other pursuits, and at a very trifling expense; and thus add largely to his yearly income.

But suppose he has no family of children of his own and is obliged to hire those of his poorer neighbors; he is then increasing his own profits by this business, at the same time that he is rescuing these children from the evils of an idle life, and giving them food to eat and raiment to wear.

There is still another view of this subject which is of great importance, particularly to the citizens of many of the Atlantic states. In all of these we find large quantities of land, either naturally poor, or so reduced by culture as to yield no profit to the cultivator. The consequence is, that the people of these states are rapidly emigrating to the more fertile regions of the west to seek a subsistence for themselves and their families; giving cause for fear, that, unless some means can be found to remove this necessity, some of those states will soon be in a measure depopulated. Now it fortunately happens, that poor, sandy, and almost worn-out lands yield the very best of silk; and although the quantity will not be so large as from more fertile lands, the profits will be such as to leave no inducement to the inhabitants to leave the homes of their fathers, in order to raise wheat, corn, tobacco, or cotton, in the fertile valley of the Mississippi.

We think we have, in the few remarks we have made, shown you sufficient inducements to make a fair trial of the silk culture. We might add many more facts if we thought it necessary, but these you will find stated more at large in the periodical publications which are devoted to this cause, and particularly in the "Journal of the American Silk Society," published in Baltimore, and to which we refer you, in the full confidence that you will there find all the directions necessary for propagating the trees, feeding the worms, and reeling the silk, as well as full and authentic intelligence as to the state of the silk market and trade—to be procured by maintaining a regular correspondence with our public functionaries and others, at home and abroad, possessing most experience and having access to the best sources of information. To commence the business upon a moderate scale will involve but a small outlay of capital; and even this will yield as speedy a return, and a much larger one, than you could hope to receive from almost any other investment.

GIDEON B. SMITH,
WM. GIBBONS,
S. R. GUMMERE.

January, 1839.

☞ Our Four First Volumes,

Have been reprinted, and a quantity of them bound, some two volumes in one, and some four in one, have been forwarded to our agents in Boston, New-York, Philadelphia, Baltimore, Washington, Richmond, Augusta, St. Louis and New-Orleans· and they will be forwarded to Hartford, and other places where they may be ordered, as soon as navigation will permit. They cannot be sent, bound, by mail; but will be sent to order in a stitched form.

☞ Receipts are often requested to be sent for moneys received. The receipts of five dollars and over will be acknowledged in the Cultivator; and for less sums, the receipt of the papers for which money is sent, by the subscriber, is an acknowledgement that we have received it. This arrangement will save the writing of many letters and much postage.

Mulberry seed, we are desired to advertise the public, is for sale by W. Coleman, bookseller, New-York, and by J. F. Callan, bookseller, Washington City.

*Moneys received during the last month, in sums of five dollars and over. The total receipts are included from post-offices marked with an asterisk.**

THE CULTIVATOR:

A MONTHLY PUBLICATION, DEVOTED TO AGRICULTURE.

I KNOW OF NO PURSUIT IN WHICH MORE REAL AND IMPORTANT SERVICES CAN BE RENDERED TO ANY COUNTRY, THAN BY IMPROVING ITS AGRICULTURE.—*Wash.*

VOL. VI. NO. 3, WASHINGTON-ST. ALBANY, N. Y. APRIL, 1839. No. 2.

Conducted by J. BUEL, of Albany.

TERMS.—ONE DOLLAR per annum, to be paid in advance. Subscriptions to commence with a volume.

Special Agents.—L. & R. HILL, Richmond, Va.; BELL & ENTWISLE, Alexandria, D. C.; GIDEON B. SMITH, Baltimore, Md.; JUDAH DOBSON, bookseller, D. LANDREITH, and M. S. POWELL, seedsmen, Philadelphia; ISRAEL POST, bookseller, 88 Bowery, ALEX. SMITH, seedsman, P. WAKEMAN, office of the American Institute, Broadway, N. York; HOVEY & Co. Merchants' Row, Boston; ALEX. WALSH, Lansingburgh, and WM. THORBURN, Albany, gratuitous agents. For general list of agents see No. 12, vol. v.

The Cultivator is subject to common newspaper postage.

☞ The published volumes are for sale at the subscription price, or, if bound, the cost of binding added. The bound volumes may be also had of our Agents in the principal cities.

THE CULTIVATOR.

TO IMPROVE THE SOIL AND THE MIND.

Agricultural Schools.

We may learn wisdom from the infidel Turk, notwithstanding the low grade in the scale of civilization in which we choose to place him. Ali Pacha, the sovereign of Egypt, rightly appreciating the value of agricultural improvement in his dominions, has established, among other national schools, one for instruction in the theory and practice of agriculture, and another for instruction in the veterinary science. When shall we become as wise in these matters as the Pacha of Egypt? Answer—when our representatives are willing to forego personal and sectional aggrandizement to promote the common good; when they will make patriotism, which consults the good of the whole, paramount to the contracted notions which yoke them to the car of party—to the interests of a few aspiring individuals.

Premiums for 1839.

We offer the following premiums for the current year—the time for competing for the first to terminate on the first of September, after which the essays and drawings already received, and which may be received, or at least such as may be deemed to possess the most merit, will be published. The essays, &c. for the other premiums, will be received any time before the tenth of January next, and will be published in the February and March numbers.

1.	For the best plan of a farm dwelling-house, of stone, brick or wood, to cost from $600 to $2,000, a premium of	$20 00
2.	For the most profitable acre of corn,	10 00
3.	For the second best do	5 00
4.	For the most profitable acre of ruta baga,	10 00
5.	For the second best do	5 00
6.	For the most profitable acre of mangold wurzel,	10 00
7.	For the most profitable acre of sugar beets,	10 00
8.	For the most profitable acre of carrots,	10 00
9.	For the best sample of ten pounds of beet sugar produced by household process,	10 00
10.	For the best sample of ten pounds of Maple sugar, produced in the like way,	10 00

Note.—Plans of dwelling-houses must be accompanied by drawings of the elevation and ground plan, and must comprise estimates of expense for wood, brick or stone. The sugar must be presented before next new-years' day. To give uniformity, labor in raising the crops must be estimated at $2 per day for man and double team, $1.37½ for man and single team, 75 cents for man, and 50 cents for every load of manure, when spread. The same statements of modes of culture, labor, expense, produce and profits will be required as heretofore, and the same evidence of the credibility of the competitor. The product of corn must be over 80, and of the roots over 600 bushels per acre.

Useful Mode of Teaching.

We have been very much interested, and highly gratified withal, by the perusal of a letter from E. E. Barney, principal of an academy at Dayton, Ohio, detailing the mode of instruction pursued with some classes of young men under his charge. The letter was not written for the public eye, but preliminary to a request to know at what discount we would put a number of Cultivators to serve as a class-book. We very willingly replied, that for such a noble object, we would discount one-third of the subscription price, a proposition which will be extended to any academy, which may choose to adopt Mr. Barney's excellent example. In the letter accepting our proposition, we have permission to publish Mr. Barney's mode of instruction, which follows.

"In the academy of this place, of which I have charge, I have a class in reading of forty boys. I have taken the Common School Assistant, one for two boys: when the class are called for reading, I distribute to them the papers, with the injunction, that no scholar turn over a leaf, or look at any other part of the paper, till the first page is read in order. Sometimes only one scholar reads; the rest of the hour is taken up in commenting on the subject read, and in answering questions and inquiries suggested to the minds of the class, by the topic under consideration. Thus topics of interest, and such as elicit discussion, are constantly coming up. We always have something new, as none are permitted to look upon any part of the paper, except that containing the lesson for the day. At the close of the recitation, the papers are taken away and locked up. This frequently happens in the midst of an interesting discussion, when every member of the class is anxious to express his opinion—(which they manifest by raising the hand, none speaking without permission)—and thus they return to the recitation with increasing interest each day. * * * *

"I have taken the Cultivator from the beginning, and consider it invaluable to the farming interest. Many of the boys in the first named class are studying chemistry. I have read many extracts from the Cultivator to them, showing how a knowledge of this science would aid an intelligent farmer in cultivating the soil. The result has been, that many of the class now view farming in an entirely new light. *They had before looked upon it as only fit for the ignorant and clownish;** but many of them now view it as a profession, *to be studied and learned, and worthy the time and attention of the most gifted intellect. Many who had before been hesitating in the choice of a business for life, begin to look upon farming as combining the three requisites*—HONOR, PROFIT *and* HAPPINESS."

"At the end of the year, the papers can be bound in volumes, to be used again by other classes. At the close of each paragraph, the class are permitted and encouraged to ask questions, on the subject read. The teacher also questions the class, and ascertains not only that each word is understood, but that the general scope and bearing of the whole subject is comprehended. If this course be adopted and carried out fully, it will enable the teacher to communicate a vast amount of knowledge in the most agreeable form, and in a way that will be treasured up by the pupil. And more than this, he will be able to mould the mind of the pupil to habits of correct thinking, to eradicate error, and to instil right principles—a matter more important than any other in education. The amount read, in learning to read, is of little consequence,—every thing depends on the manner. Again, it is of little service to learn to call the words correctly, unless the pupil be so instructed that each word is a picture to the child's mind of an idea. And even the advantages of this instruction is problematical, unless such principles be inculcated at the same time as will insure the right application of such knowledge in after life.

"It is for these reasons that I have adopted the plan here detailed. My experience thus far most fully sanctions it."

School-Houses.

We have been obligingly favored with the report of the Secretary of the Massachusetts Board of Education, on the subject of school-houses. No person can read it without being forcibly struck with the glaring defects which are seen to exist in most school-houses of the present day, and some of which are calculated to produce the most serious and lasting evils upon teachers and children. Gen. Mann has discussed the subject under the heads of *Ventilation and warming—Size—Desks, seats, &c.—Location of school-houses—Light—Windows—Yards or play grounds*—and *the duty of instructors in relation to school-houses.* He has also submitted plans of school-houses; and subjoined letters from gentlemen of medical and scientific celebrity in confirmation of the opinions he has advanced.

Considering the subject one of great importance to the whole community, and one that has been but little investigated, or understood, we shall attempt to give a brief abstract of the report, and accompany it with two of the plans.

Ventilation and warming.—The importance of pure air to health, we have particularly explained in an article upon that subject, in another column, the perusal of which we think will satisfy every reflecting mind, that children in a crowded school, especially in winter, suffer seriously, and often fatally, from the confined and vitiated air of school-rooms. Dr. Woodward has stated, that in a close room of thirty feet square, and nine feet high, fifty scholars will so poison the air by breathing, that in forty minutes it is wholly unfit for respiration. One of the strongest cases cited, of the destructive influence of air which has become vitiated by breathing, is that of the Black Hole in Calcutta, a room eighteen feet square, into which one hundred and forty-six persons were thrust, and kept confined for ten hours; and although there was one aperture for the admission of air and light, one hundred and twenty-three had perished at the end of that time. Only twenty-three survived, and several of these were immediately seized with the typhus fever.

To obviate the evils incident to foul air, there is wanted, the secretary observes, "a current of fresh air flowing into the room, while a current of the respired air flows out of it; both to be equal to the quantity required for the occupants. Under such circumstances, if there be but little motion in the room, the poisonous part of the air [carbonic acid gas,] will settle towards the floor as soon as it is cast from the lungs, while the other part of it, being raised almost to a blood heat in the lungs, will rise to the ceiling. In the ceiling, therefore, should be an aperture for its escape. The carbonic acid will tend to flow out under the door, or when it is opened. If the ceiling be concave or dome-shaped, only one aperture will be necessary; if horizontal, and the room be large, several may be required. These apertures may open into the attic, into the side walls, or into the chimney; and the flues to conduct off the impure air may have valves, or dampers, to be opened or closed at pleasure. For the introduction of fresh air, the report recommends, that a cellar be constructed under the school-house, for the deposite of wood, and the construction of a furnace, the brick or soap-stone top of which may be level with the floor, and one or two orifices will admit a constant stream of heated air from the cellar into the school room. If a stove is employed, it should be enclosed by a sheet iron case, rising from the floor on three sides of the stove, and bending over it; not, however, so as to *close* over its top, but leaving an opening in the case greater or less, according to the size of the stove and the room.—The fresh air to be introduced into this case from out-of-doors, by a conductor through the floor. A thermometer should be kept in the school room, and the temperature made to range from 65 to 70°.

Size.—In the improved penitentiary system, at Charlestown and Philadelphia, 171 in the former, and 1,300 in the latter, cubic feet of air are allowed to each prison cell. In a room thirty feet square, and twelve feet high, there would be 10,800 cubic feet, which, divided among twenty inmates, would afford to each 540 cubic feet, double the amount allowed to a Massachusetts convict, but less than a half that is allowed to one in the Pennsylvania penitentiary.—The cases are greatly dissimilar; and the advantage is altogether in favor of the school room, in consequence of its greatly superior facilities for the admission of fresh air. Yet the comparison will serve to show, that even in punishing the wicked, we are not disposed to withhold from the convict, this first blessing of heaven—pure air—towards the enjoyment of life. Our school-houses are undoubtedly too small, and too low, in general, for the number of scholars which they are intended to receive. In our estimate, we calculate rather how many we can *pack*, than how many we can accommodate. By a narrow, short-sighted parsimony, we endanger that which we are most desirous to preserve—the health of our children. A school room should be so large, as to afford room for all the seats and desks for the pupils, and to leave an "open space all round the walls, at least two feet and a half in width, besides room for the common recitations and the teacher's desk," with anti-rooms or halls for the children's hats, bonnets, &c.

Desks, seats, &c.—A level floor is recommended, as increasing the space for air, and as promoting an equilibrium of temperature. "The seats with desks should be arranged in parallel lines, lengthwise of the room, with aisles between, each seat to accommodate one scholar only. Eighteen inches is perhaps a suitable width for the aisles. Each desk should be two feet long, and not less than one foot six inches, or nine inches wide." With regard to seats, an awful neglect has been too generally manifest—1st, in not making them broad enough; 2d, in not so adapting them that the feet of those sitting upon them may rest firmly on the floor; and 3d, in not providing backs to them. As to the tendency of these defects in our school rooms, upon the human system, we quote Dr. Woodward. He says:

---

* It is feared that farmers who seek to elevate their sons and themselves, by sending the former to the liberal or mercantile professions, as well as the statesmen, who neglect to foster this great business, have the same contracted notions of a business which puts in requisition our best and noblest faculties.

"*High* and *narrow* seats are not only extremely uncomfortable for the young scholar, tending constantly to make him restless and noisy, disturbing his temper and preventing his attention to books, but they also have a direct tendency to produce deformity of the limbs.

"If the seat is too narrow, half the thigh only rests upon it: if too high, the feet cannot reach the floor; the consequence is that the limbs are suspended on the centre of the thigh. Now as the limbs of children are pliable or flexible, they are easily made to grow out of shape, and become crooked by such an awkward unnatural position.

"Seats without backs, have an equally unfavorable influence upon the spinal column. If no rest is afforded the backs of children while seated, they almost necessarily assume a bent and crooked position; such a position often assumed, or long continued, tends to that deformity which has become extremely common with children in modern times—and leads to disease of the spine in innumerable instances, especially with delicate female children.

"The seats in school rooms should be so constructed, that the whole thigh can rest upon them, and at the same time the foot stand firmly upon the floor; all seats should have backs high enough to reach the shoulder blades; low backs, although better than none, are far less easy and useful than high ones, and will not prevent pain and uneasiness, after sitting a considerable time. Young children should be permitted to change their position often, to stand on their feet, to march, and to visit the play ground. One hour is as long as a child, under ten years of age, should be confined at once, and four hours as long as he should be confined to his seat in one day."

"At this period of life," says the report, "when portions of the bone are but little more than cartilage, and the muscles will stretch like sheep's leather, the question is, whether the seats shall be conformed to the children, or the children shall be deformed to the seats."

"Young persons," remarks Dr. Warren, "however well disposed, cannot support a restriction to one place and one posture. Nature resists such restrictions; and if enforced, they are apt to create disgust with the means and the object. Thus children learn to hate studies, that might be rendered agreeable, and they take an aversion to instructors, who would otherwise be interesting to them."

"In the course of my observations," continues Dr. Warren, "I have been able to satisfy myself, that about half the young females brought up as they are at present, undergo some visible and obvious change of structure; that a considerable number are the subjects of great and permanent deviations; and that not a few entirely lose their health from the manner in which they are reared. I feel warranted in the assertion, that, of the well-educated females, within my sphere of experience, about *one-half are affected with some degree of distortion of spine*. The *lateral* distortion of the spine is almost wholly confined to females, and is scarcely ever found existing in the other sex. The posture females assume, while seated at their studies, are not indifferent. They should be frequently warned against the practice of maintaining the head and neck long in a stooping position, and the disposition to it should be lessened, by giving a proper elevation and slope to the desk, and the seat should have a support or back."

Location of school-houses.—After pointing out the injurious influences which result from placing the school-house in a bleak or marshy situation—upon a sandy plain, without shade—or upon the road-side, amidst the dust of travel, and where the children's attention is constantly called off by the passers by—or upon a little delta of land, surrounded by roads, without any place of seclusion from the public gaze, and where the modesty of nature will be overlaid by habits of indecorum;—after pointing out the objections to such locations, the report directs—"Build it where some sheltering hill or wood mitigates the inclemency of winter; where a neighboring grove tempers the summer heat, furnishing cool and shady walks; remove it a little from the public highway, and from buildings where noisy and clattering trades are carried on; and, above all, reserve it from sound or sight of all resorts for a license for dissipation; and a sensibility to beauty, a purity of mind, a sentiment of decency and propriety, will be developed and fostered, and the chance of elevated feelings and correct conduct in after life will be increased manifold."

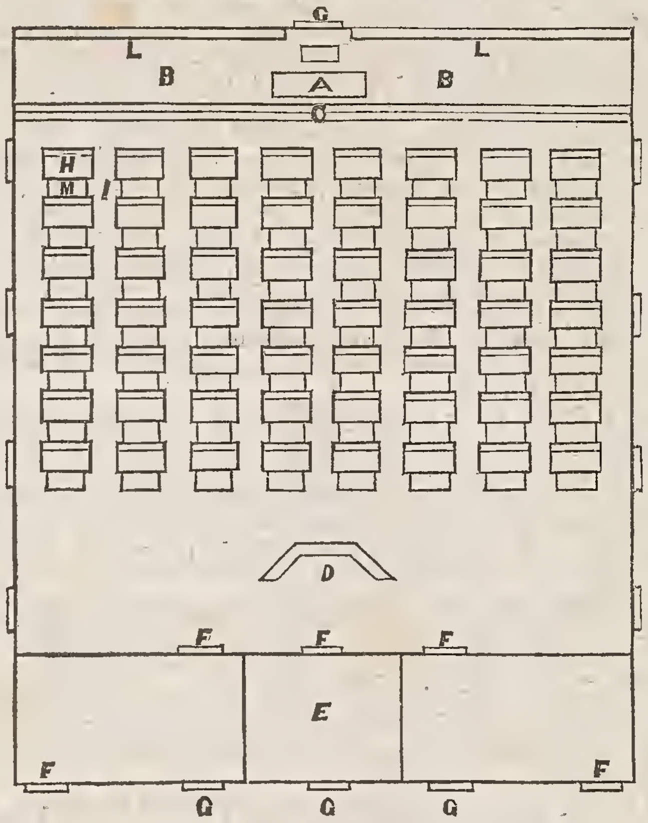
Light and windows.—"The windows should be such as to furnish sufficient light at all times," and should be furnished with blinds and curtains for excluding any excess, which often proves prejudicial to the sight of children. The windows should be made so that the upper sash can be lowered, or the lower sash raised.

Yards or play grounds.—Much emphasis is laid upon these being sufficient for the play and exercise of the children, and of their being kept neat and cleanly. "With the number who ordinarily attend these institutions, not less than a quarter of an acre, [in the country,] should ever be thought of as a space for their accommodation, and this should be enclosed from the public highway, so as to secure it from cattle, that the children may have a safe and clean place for exercise at recess and other times." It should contain some "ornamental and fruit trees and flower borders, which children may be taught to cultivate and enjoy, and by an attention to which their ideas of property, and common rights and obligations, would become more distinct. By attention to what belonged to themselves, they would be kept from many of those wanton injuries too often done to the possessions of those near them."

The duty of instructors, among other things, is declared to be, to see that the school-room in all its parts, be kept in a clean and comfortable condition, as being highly conducive to the observance of this virtue in the children, and to their correct deportment.

The report concludes with recommending, that every school-house have a bell, to inspire punctuality and order; a time-piece, where it can be seen by the scholars, as an encouragement and relief, like that felt by the traveller in seeing mile-stones;—a well or a spring, from which a ready supply of water may be obtained;—scrapers and mats at the doors and in the halls;—and, where there is no cellar, a shed for wood—the latter being deemed indispensable.

EXPLANATION OF THE PLATES.



[Fig. No. 4,]

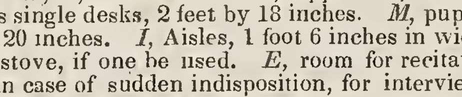
Represents the general plan of a school-house, as recommended in the report. *A*, teacher's desk. *B, B*, teacher's platform, from 1 to 2 feet in height. *C*, step for ascending the platform. *L, L*, Cases for books, apparatus, cabinet, &c. *H*, pupils single desks, 2 feet by 18 inches. *M*, pupils seats, 1 foot by 20 inches. *I*, Aisles, 1 foot 6 inches in width. *D*, place for stove, if one be used. *E*, room for recitation, for retiring in case of sudden indisposition, for interviews with parents, when necessary, &c. It may, also, be used for the library, &c. *F, F, F, F, F*, Doors into the boys' and girls' entries—from the entries into the school-room, and from the school-room into the recitation room. *G, G, G, G*, windows. The windows on the sides are not lettered.

The seats for small scholars, without desks, if needed, to be moveable, and placed as the general arrangements of the school shall render convenient.

Where there is but one teacher, the space between the desks and the entries to be used for recitation. Here, also, is the place for black boards, whether moveable or attached to the wall. This space should be 8, 10 or 12 feet wide, according to the size of the school.

The height of the room should never be less than 10 or 12 feet.

[Fig. No. 5,]



Represents an end view of the pupils' desks and seats. *J*, pupils' seats. *K*, shape of the board or plank which forms the side and support of the desks.

A light green is perhaps the best colour for the scholars' desks and seats, as it is more grateful than any other to the eye. For the outside of the house, white is the colour most universally pleasing.

PLAN OF A VILLAGE SCHOOL-HOUSE.

[This is the plan submitted to the American Institute of Instruction, by their board of Censors, in 1831.]

[Fig. No. 6,]

"Is the ground plan of a village school-house, for both sexes, containing eighty separate seats and desks. Additional seats for small children, who may not require *desks*, can be introduced at pleasure, and the teacher can arrange them in such situations as may be most convenient. For this purpose, a sufficient number of light, moveable forms should be furnished.

"The whole edifice, exclusive of the portico in front,—which may be omitted, if a cheap, rather than a tasteful building is required,—is 58 feet long, and 35 feet wide. The dimensions of the *school-room* allow 21 feet of floor to each of eighty scholars, the passages, teacher's platform, &c. being included. It is believed that this allowance is not too liberal,—is not more than is required for the comfort, health and improvement of the scholars.*

"The plan here proposed may be enlarged or diminished, for a greater or less number of scholars, according to the following scale:—For ten scholars, add 4 feet to the length; for sixteen scholars, add 4 feet to the width; for twenty-eight scholars, add 4 feet to both length and width. For a less number of scholars, the length, or breadth, or both, may be diminished at the same rate.

"The *school-room*, represented in the plan annexed, is 48 feet long, and 35 feet wide, within the walls.

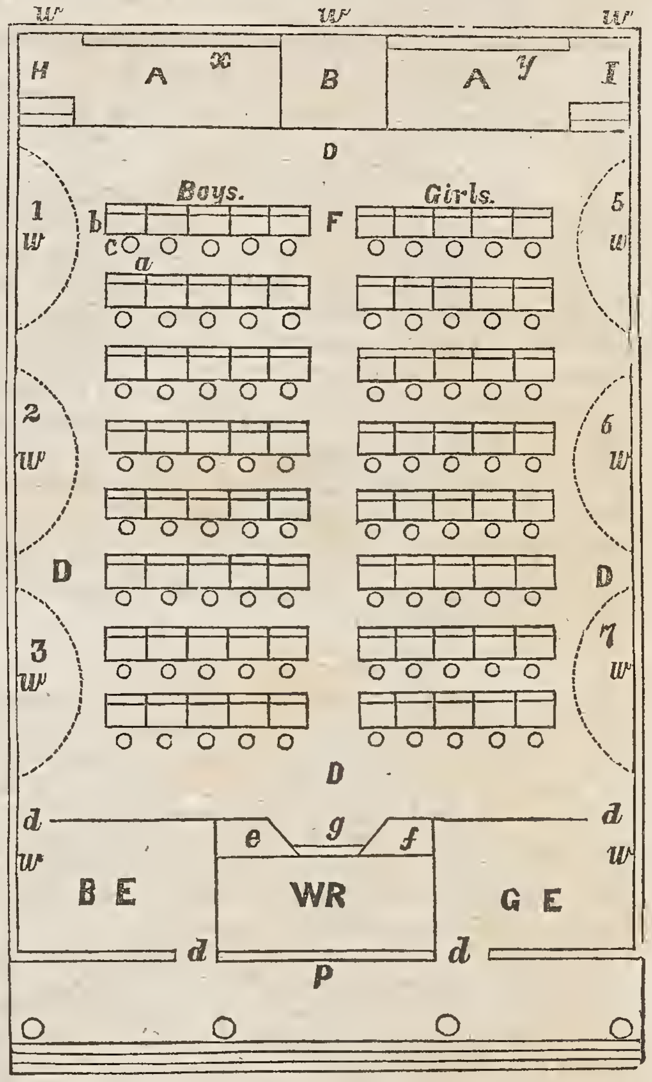
"*The floor of the room should be level, and not an inclined plane.* Nothing is gained by the common mode of finishing school rooms with inclined floors; and much is lost in symmetry, convenience and comfort. A faithful and active teacher will be about among his scholars, and not confine himself to a fixed seat, however favorably situated for overlooking them.

"Whether there be a stove in the school-room or not, there ought to be an open fire-place, where children may warm and dry their feet. The fire-place should be furnished with a hot-air chamber, to facilitate the ventilation of the room.

"The lids or tops of the scholars desks are usually made to slope too much. They should be nearly, if not quite horizontal,—an inch to a foot being a sufficient slope.

"Each scholar should have a separate seat, which should be confined to the floor. The seat should be about 13 inches square.

"The *front* rows of seats and desks, or those nearest the master's platform, being designed for the smaller children, should be lower than those near the entries."



Explanation.—*P*, doric portico in front of the school-house. *d, d, d, d, d*, doors. *B, E*, boys' entry, 12 by 10 feet. *G, E*, girls' entry, 12 by 10 feet. *W, R*, wood-room, 11 by 8 feet. *g*, fire-place. *e*, closet. *f*, sink, to be concealed by a falling door balanced with weights. *D, D, D, D*, passage around the room, 6 feet wide. 1, 2, 3, 4, 5, 6, stations marked on the floor, to be used by classes, when reciting to monitors. *A, B, A*, the teacher's platform, extending across the room, 6 feet wide and 9 inches high. *B*, a part of the platform to be removed in the winter, if necessary, to make room for a stove. *x*, cabinet for apparatus, specimens, &c. *y*, book-case. *H*, master's desk. *I*, assistant or monitor's desk. *F*, centre passage; in the plan drawn 3 feet wide, but 4 feet would be better. *b*, scholars' desks, 18 inches wide and 2 feet long.—*c*, scholars' seats. *a*, passages between the seats and next row of desks, 13 inches wide. A desk, seat and passage occupy 4 feet, viz: desk 18 inches, space between the desk and seat 2 inches, seat 13 inches, and passage 15 inches. *w, w, w*, &c. windows, which should be placed high from the floor.

Root Culture.

II.—BEETS,

Of whatever variety, whether for sugar or for cattle, require the same soil and the same culture. The mangold wurzel, or scarcity beet, has hitherto been the principal kind cultivated for farm stock, though the blood beet has been occasionally, and the sugar beet recently—both grown for this purpose.

Beets, like all tap-rooted plants, require a deep soil, as it seldom happens that the roots enlarge much in the subsoil, or below where the earth is moved by the plough or spade. Moist loams, either of sand or clay, suit them best; though they grow on all soils not wet or very stiff, provided they are made rich and mellow. The mangold wurzel will do better on poor lands than the other sorts.

The deeper the ground is ploughed, the more thoroughly it is pulverized, and the more intimately the manure is incorporated with the earthy matters, the better prospect of a crop. Pulverization is particularly necessary to the germination of the seed. The harrow should therefore be efficiently used before the seed is deposited in the soil.

---

* "It may not be amiss to state, that two of the Censors teach large private schools in Boston; and in their respective schools, they allow, for each of their scholars, about 22 square feet of floor, exclusive of entries, dressing rooms, recitation rooms, &c. One of the school-rooms is 16 and the other 18 feet high—the former giving about 350, and the latter about 400, cubic feet of space, to each scholar."

The manner of planting the beet, of whatever kind, is in drills, which may be done either by the drill-barrow, or from the hand. Mangold wurzel should be in rows twenty-seven to thirty inches apart, and the plants, when out of the reach of insects, thinned to twelve or fifteen inches in the row, as the object is to obtain large size. The table and sugar beet may be grown in rows from twelve to twenty-four inches apart, and may be left to grow at six to ten inches in the rows—the object being not great size, but good quality—and it being found that the quality of medium or small sized roots, is better both in regard to flavor and saccharine matter, than that of very large roots. Some prefer soaking the seed, and some even sprouting it, before it is sown; as it is husky, and in case of dry weather, frequently does not germinate. But if the seed is put into fresh ploughed ground, planted early in the season, and a roller passed over the surface after it is covered, or the ground pressed with the hoe or foot, the seed seldom fails to grow. The seed should be covered three-fourths to an inch deep; and as the young plants are liable to be destroyed by the grub, and even turnip fly, it is advisable to sow thick, say from three to four pounds of seed to the acre.

In the after culture the objects are to keep the crop clean, and the soil mellow. The first dressing may be light, with a cultivator, where the breadth between the rows will admit; but when the plants are well established, the cultivator, or small plough, should be run deeper, and this operation may afterwards be repeated to advantage. The crop should be harvested as soon as it has ceased growing, which is known by the under leaves turning yellow; as if left in the ground longer, the roots deteriorate in value.

Mangold wurzel is the German name; mangold a *beet*;—wurzel, a *root*. Their culture was introduced into England, from Germany, about 1820, and more recently they have attracted considerable attention in this country. In 1830, the Doncaster Agricultural Association, an institution which has rendered vast service to the farming interest, sent abroad a circular, among the best English farmers, with a view of collecting all the information upon the culture and use of this vegetable, which was likely to be useful. Nineteen answers were received, from large growers of the root, and the society published, in a condensed form, their purport. The report states, that

> "The answers are from every description of soil, the greatest number (nine) from sand, not, it appears because that kind of soil is most favorable to it, but because on sands, fallow crops, of all sorts, are more generally grown than any other; six are from peat, four from clay, four from chalk or lime-stone.
>
> "The method of sowing appears to be drilling or dibbling on ridges, from twenty-seven to thirty inches apart, and afterwards singling out the plants in the rows, at about sixteen or eighteen inches from each other: the period of sowing, any time between the middle of April and end of May; on cold soils earlier than on warm.
>
> "The tops and leaves should be ploughed into the land immediately.* In comparing the quantity of manure used for Swedish turnips and mangold wurzel, it appears from the answers of those farmers who have tried mangold wurzel longest, that both require nearly an equal quantity, ten or twelve two horse cart loads per acre. With respect to the comparative product of the two crops, it appears to be in favor of mangold wurzel in the proportion of about one-fifth. The greatest weight obtained is by Mr. Simpson, of Babworth,—54 tons. Of our correspondents, ten decidedly prefer mangold wurzel, two give a partial preference to Swedes, and the rest have not expressed an opinion.
>
> "The feeding properties of mangold wurzel and Swedes are an important part of our investigation. Lord Althorp alone has tried their comparative merits; and he gives them a decided preference over the Swede. In this opinion his lordship is supported by Mr. Kelk; but seven of our correspondents are of the opinion that the Swedish turnips will feed quicker. Five of our correspondents say it is beneficial to milch cows, and two of the Norfolk farmers say it is apt to injure the butter.
>
> "To sum up—the advantages of mangold wurzel are these—
>
> It is more sure to plant, being very little liable to the fly or grub.
> It will produce more weight.
> It is off the land earlier.
> It is useful as a change of fallow crop when the land is tired of turnips.
> It will grow on land where turnips cannot be raised.
> It is better spring food.
>
> "On the other hand, in favor of the Swedish turnips it may be said—
>
> That the weeding and singling out are less expensive.
> There is more time for fallowing in the spring.
> The succeeding crop is better than after mangold wurzel.
> Perhaps cattle feed best on Swedish turnips when they are fed alone."

Mangold wurzel is relished by every description of stock; though in feeding it to neat cattle, it is recommended to commence with small feeds, and when it produces bad effects, to change the animal's food for a few days. Charles Poppy, an enthusiast in this culture, and whose pamphlet is before us, particularizes twenty-six uses to which this root may be profitably applied.

The British farmers speak highly of this root as a food for young calves. It is cut small, and fed to them after they are a fortnight old, with wonderful benefit.

The value of this crop is certainly great in the economy of the farm. Estimating the product at twenty tons an acre, it will give 746 bushels of sixty pounds each; which, at the rate of two bushels a day, would keep a cow, with the addition of a little straw or chaff, 373 days, or somewhat more than a year. Two tons of hay, the average product of an acre, would keep the same animal, allowing a quarter of a hundred per diem, but 160 days, or about one-third of the time that the wurzel from an acre would keep her—and the animal would be better, in flesh and milk, on the roots than she would be kept on the hay.

In storing and keeping the mangold wurzel in winter, the same precautions must be taken, and the same means must be adopted, as are required for securing potatoes and ruta baga. If deposited in pits, these should be narrow, and ventilating holes made in the crown of the pits. They are more liable to be injured by frosts than the ruta baga.

III—THE CARROT.

Col. Meacham has anticipated us in giving the culture and profits of this root, in his communication published in our last. Nevertheless we will throw all the new light upon the subject which our experience and our reading afford.

The soil best adapted to the growth of the carrot is a deep sand loam. The preparation of the ground consists in ploughing to the depth of a foot, the application of rotten manure, to be well incorporated with the soil—except long manure has been applied to the previous crop—and complete pulverization. Ploughing the fall previous for the crop is recommended.

The kind of carrot best adapted to field culture is the long red. The seed should be of the preceding year's growth. The mode of culture is best in drills, though in Suffolk, England, sowing broadcast is preferred. We have modern drill-barrows adapted to the sowing of this seed, though the sowing it by hand is not a tedious process—as a man may go ahead in sowing in this way as fast as another drives a barrow. The difference consists in making the drill with the hoe and covering the seed. As the seed is of peculiar lightness, it is apt not to vegetate well if the surface is light; and the practice has obtained, with large growers, of preparing it before hand, by mixing five pounds of seed with a bushel of sand or fine mould, a week or two before hand, and of moistening and turning the mass frequently; by this means not only do all the seeds grow, but the plants come up quickly, and get the start of weeds. Two pounds of seed is enough for an acre when sown in drills, though five pounds are often sown on an acre broadcast. Von Thaer uses poudrette, instead of mould, in the preparation of his seed. The drills should be eighteen inches apart, and the plants thinned to six or eight inches. The seed should be sown early in or by the middle of May.

The after culture of carrots consists in keeping them free from weeds, and the surface of the soil open; and as the rows are too near to admit of the plough or cultivator, the hand hoe must be depended on.

The best mode of harvesting the crop is that adopted by Col. Meacham—turning the earth from the row with the plough, and then drawing them with the hand.

The ordinary yield of the carrots is less than that of ruta baga or mangold wurzel—the average may be stated at 400 to 500 bushels the acre, though the product has exceeded 1000. They are so hardy, that in the south of England they are permitted to stand out in the winter; but with us they should be gathered and secured like other roots, in October.

The carrot is eaten by all sorts of farm stock, but is particularly useful for horses and milch cows, serving as a substitute for grain with the former, and increasing and improving milk when fed to the latter: Mr. Burrows, one of the greatest growers of this root, has fed ten cart horses with them, during the winter months, and up to June, with hay, and without the addition of grain. Such does he consider their economy in horse feeding, that he states, as demonstrated by his experience, that with the assistance of lucerne for soiling in summer, a workhorse may be kept the entire year round upon the produce of only one acre of land. Mr. Burrows feeds seventy pounds a day to a horse, cut or whole, and mixed with chopped hay—reducing the quantity somewhat in the short days of winter, and increasing it a little in the spring months. Other growers feed only forty or fifty pounds a day. An acre of carrots, yielding 600 bushels, fed fifty-six pounds a day, would therefore be equivalent to 300 bushels of oats, fed half a bushel a day, to a working horse.

To save seed, save select roots, and keep them in sand in the cellar till spring, plant them out early, and the seed will be ripe in August. Preserve it on the seed stalks till wanted.

IV.—THE PARSNIP,

Is generally believed to be more nutritive than any of the roots we have treated of; the product to be greater than that of the carrot or potato, with the advantage over them both, that the parsnip is not injured by frosts. Yet its culture as a field crop has hitherto been very limited.

The parsnip may be grown on stiffer land than the other roots we have named, provided it has a rich deep tilth. It requires the same treatment as the carrot, though we would prefer intervals of eighteen inches between the rows, as in good soil the tops grow large. The Jersey variety is preferred, on account of small growth of top. Sow early, at the rate of four or five pounds of seed to the acre, and keep the crop free from weeds.

The Silk Business,

Notwithstanding all the reaction it is likely to encounter from the extravagance of the Morus Multicaulis speculation, will, nevertheless, yet become a great business in our country, and one of certain profit to the farmer who embarks in it—not as a dependence, or a speculation, but as a collateral branch of his farming operations. Let no one give up for the mulberry, the culture of grain, grass, or roots—or omit the rearing of cattle, or the ordinary means of increasing the fertility and profits of his farm. Let the course of general improvement of the farm go on. But at the same time, with a small outlay, he may begin to plant the mulberry—not upon his best fields—but upon his waste grounds—upon such as are dry and stony—along his division fences, and about his buildings, where they will least interfere with his ordinary farm products. He may plant them in hedges. A few thousand eggs, will cost but a trifle, when his trees are sufficiently advanced to yield foliage to feed his worms. The business of gathering the leaves, and taking care of the worms, is but one of 30 or 40 days. It can be done altogether by the inmates of the family, without taking any thing from the ordinary labors of the farm. It can be done, and should be done, by the women and children. No expensive cocoonery is necessary for farm purposes. A room in the dwelling, or a shed, to protect the worms from the weather, may be spared on almost any farm, for the small time it is wanted for this purpose. The silk which is produced in this way, may be considered a clear gain to the family which produces it, be it fifty dollars, or be it five hundred dollars.

In regard to the kind of mulberry to be cultivated, we really feel incompetent to advise. We do not believe there is any great difference in the value of the silk which is made from the different varieties of the mulberry. One may be of finer or softer appearance, another of more substantial fabric, but all of intrinsic value, and adapted to particular purposes. The preference given to large leaves, we think less of, than most others do: for we are induced to believe, that the Asiatic mode of taking the young twigs, instead of the leaves only, for the worms, is preferable, as the first will remain succulent and fresh the longest. And if planted in hedge, a dozen bushels may be taken in so many minutes, with a bill-hook, and without prejudice to the hedge. So that in our opinion, the principal question to be decided by those who intend to grow them for their own use, is, what kind is best adapted to one's soil and climate.

Those who will submit to the trouble of taking up the multicaulis in the fall, and re-planting it in the spring—or of cutting it to the ground, and covering the stump during winter, will perhaps best subserve their interest by selecting this variety; though if they expect to have it withstand our severe winters, unscathed, in the open ground, except in solitary instances, and in peculiar dry and poor soils, they will certainly be disappointed. The same remarks, will in some measure apply to the white mulberry, in the country north of Albany. We have tried both the multicaulis and the white mulberry for years; the first has died wholly, and the last partially.

We last spring planted out some trees of the Brussa and Canton, and sowed seeds of the former, and left the trees, and a part of the seedlings, to the open exposure of the weather. The trees threw out many branches, which grew from three to four feet—the seedlings, growing very thick in garden soil, reached 15 inches. On examining them to-day, we find two to six inches of the extremities of the branches of the Brussa dead, but the main stems and branches otherwise perfectly sound and uninjured. The Canton have suffered somewhat more, about half the last year's growth being killed—though their position for ripening the wood, was not so good as that of the Brussa. The Brussa seedlings are killed down a third to a half of their growth. These were in luxuriant growth, and consequently tender, when the frosts of autumn came upon them. From this experiment, we are led to infer, that both these species of the mulberry may be planted in this latitude with tolerable prospects of success. We think them both more hardy than the white mulberry, and much more hardy than the multicaulis.

---

* After the roots are harvested.

Of several new kinds of the mulberry, of recent introduction, as those denominated the Alpine, Moretta, Expansa, &c., we know nothing from personal observation. The leaves of the native red mulberry, which grows in our woods, certainly produce good silk, and the tree is perfectly hardy; and it may yet become the favorite in our borean climate.

Our remarks are intended to apply to the north.—The multicaulis will unquestionably be the favorite species for the middle and southern states, on account of the facility of its rapid propagation, if for no other reason. And we were not a little surprised, on being told, a day or two ago, that numerous small green-houses had been erected in East Vermont, expressly to carry on the winter propagation of this valuable exotic. Large quantities have been sent on from Florida, to supply our market. Some trees have brought four dollars each. Judge Comstock has advertised, that he has had a large quantity in a course of growth, during the winter, in the island of Cuba, which he soon expects to have on hand for sale.

Butter Making.

A nice process of butter making, as practised by John M. Weeks, of Salisbury, Vt. is given in the *Yankee Farmer*. Mr W. makes three qualities of butter; one, he says, worth 38 cents, being the pure butterycious matter, of exquisite flavor; the second, worth 19 cents; and the last 9 or 10 cents, a gluey substance, and insipid in taste. Mr. W. heats his milk, after the animal heat has passed from it, but to what temperature he does not say, and then sets his pans in cool running water; and when cold, they are raised, and the milk skimmed in 6 to 18 hours. We *guess*, for the gentleman has not told us, that the first skimming is made before the milk is put into the running water, or perhaps before it is heated, and the last, at the end of the 18 hours. The butter is salted and worked when it comes from the churn, worked again the next day, without cold-water in any of the processes, and then packed tight in tubs, lined with bags, previously saturated with bees-wax, and covered on the top with a clean pickle. The great requisites in making and preserving good butter, are:

1. That every thing should be cleanly in the whole process.
2. That the milk should be kept at a proper temperature, say from 45 to 55°, while the cream is separating.
3. That the cream should be taken off and churned, before its quality is impaired.
4. That its temperature should be from 55 to 65° when put into the churn, and the churning should be moderate and uniform.
5. That salt, of the best quality, in sufficient quantity to suit the palate, should be blended with it at the first working, and the buttermilk completely got out by the butter ladle.
6. That the working of the butter should be repeated at the end of 24 hours, when the salt has become completely dissolved, and all the liquid extracted—and,
7. That it should be packed, without more salt, to make it weigh, in stone jars, in wooden firkins or tubs, such as will not impart to it any taint or bad flavor—and in such manner as will totally exclude the atmosphere.

Butter made in this way, will be of fine flavor; and if put down and kept in this way, the flavor will be preserved for an almost indefinite period, if kept in a temperature below 70°. Water, mixed either with the milk, the cream, or the butter, and especially soft water, adds nothing to, but materially abstracts from richness of flavor. We have no doubt of the position assumed by Mr. Weeks being correct, that milk skimmed at three several times, will give three qualities of butter—that being taken off first being the richest and most valuable.

The common remark of our good butter-women, is, that "my butter is good enough"—and many think so, whose butter is very inferior. But as the principal object of the dairy-woman is gain, and as butter will sell according to its intrinsic value, every one should seek to improve, if not to please themselves, to please their customers, and not for the sake of "filthy lucre."

Sub-soil Ploughing,

Seems to be coming into great vogue in England, and is noticed and commended at most of the agricultural shows. It produces a great increase of crop; though it is not likely to supersede furrow-draining, but after the latter, especially upon stiff clays, its effects are capital. A communication was made to one of the local societies by Mr. Harrison, stating the expense of draining and sub-soil ploughing nine acres, very heavy clay, the furrow drains cut at 15, 20, 30, and 40 yards, in parallel lines across the field, before the sub-soil plough was introduced. The expense was £7 6s.—($32 40,) the acre. The sub-soil plough was propelled by 8 horses, and attended by three men and two boys. The draining was £5 10s. and the sub-soil ploughing £1 16s. The sub-soil plough for light lands weighs 200 or 250 lbs—for stiff clays 400 lbs. Price from £5 10s. to £8.

American Mulberry.

A gentleman in Kentucky has been for some years engaged in feeding silk worms on the leaves of our indigenous mulberry. He sells sewing silk annually to the amount $900, besides clothing his family. He has been offered the multicaulis, Brussa and other kinds, but he has declined them all, and sticks to the native. We have this information from a gentleman from Kentucky, who is his neighbor, and who adds, that he, the silk culturist, lately married a daughter, who was clothed in silk from his domestic establishment. Our informant calls the mulberry black, but we rather think it is the red (*M. rubra*) of botanists, as the former is not known to be indigenous; and as the berries of the red are black when ripe.

Drill Husbandry,

We have no doubt will ultimately come into vogue among us—we mean in the culture of wheat and other grains—though for a long time its progress will be slow. At the late Preston agricultural meeting in England, the question proposed for discussion was—"the comparative advantages of the drill and broadcast systems of husbandry." Mr. Binns ably advocated the drill system, and set forth its advantages under the following heads.

1. The seed is delivered with regularity.
2. It is deposited at proper depth.
3. The weeds, during the growth of plants, are destroyed with great facility.
4. The plants cultivated receive the undivided benefit of the soil and manure, and have not to maintain a constant struggle with weeds.
5. The land by the process of hoeing, is undergoing preparations for another crop.
6. The necessity of summer fallowing is avoided.
7. By admission of the sun and air between the rows, a stronger and healthier plant is produced, and of course a heavier crop.
8. By stirring the soil it is more susceptible of benefit from the atmosphere, imbibing more oxygen, and being both warmed and enriched by the sun.
9. The roots shoot freely in pulverized soil.
10. By drilling, the farmer is enabled to have heavier crops of beans and wheat on light land.
11. Clover and grass seeds answer incomparably better in the pulverization produced by hoeing, independendent of the clearness from weeds.
12. The drills give facility for depositing smaller portions of manure with greater effect.

These advantages are all self-evident to a good farmer; and it might have been added, as a thirteenth advantage, that drilling economizes seed, though Mr. Binns rejects it, on the ground, that if the plants are thin, they throw out side shoots, which produce imperfect grain, and ripen unequally. In drill husbandry, Mr. B. affirms, fifty-six bushels of wheat have been raised on the light soils of Norfolk.

The drills employed in sowing wheat, &c. are drawn by a horse, and sow six or eight rows at a time at a required distance, dropping and covering the seed. The machine for clearing between the rows, is also drawn by one horse, and consists of a frame with six hoes fixed to it, which occupies the same space as the drill. The rate of drilling is an acre per hour. Wheat is drilled at nine inches between the rows, and barley at seven. The horse hoe is used once, and the hand hoe twice. The expense of weeding, in England, is stated at two shillings (forty-four cents) per acre.

There was, some years ago, an excellent drill presented for examination, to the Albany County Agricultural Society, by a gentleman living in the west part of Oneida county; but as then drill husbandry was little understood, and its advantages less appreciated, the machine attracted but little attention, and has gone, we believe, to the tomb of the Capulets, to spring up again, we hope, phœnix like, in a better and more popular form.

Agricultural Education.

The public attention in Europe is awakened on this subject, as well as in America; and not only are schools specially devoted to this study continually rising up, but ample provisions are being made to introduce elementary books upon agriculture into the common or primary schools

It appears from the French *Annals of Agriculture*, that there were three prizes of one thousand francs each, awarded last year in France, to three authors of elementary works upon agriculture, prepared for the use of schools; and also two gold medals, and one silver one, to the authors of three other like essays. And in the list of prizes offered for the current year, we find one of 1000 francs, for the composition of elementary books upon agriculture, for children in schools.

We make the extracts below, from the proceedings of British agricultural Societies, at the autumnal meetings, to show, that the importance of education to those who till the soil—to those who furnish the bread and meat to feed the nation, is attracting much public attention there.

"Mr. Brewsher, [in the Stafford Waldron meeting,] observed, that the system of their fore-fathers, however good, was to be much improved by the assistance of education, and the combination of science, and the exploration of the mineral and vegetable kingdoms. He also impressed upon the meeting the advantage of combining theoretical with practical knowledge."

"You never can forget, that England's greatness is based on her agriculture."—*J. Gibson.*

"Agriculture should be regarded in a more scientific point of view, [John Greg, in the Northumberland meeting,] and the principles of science applied to it. These principles ought to be followed out by men of science, for the public benefit. * * * There is a great field to be discovered here, but not by the mere practical farmer, but by the researches of scientific men. Gentlemen, in prosecution of subjects of this kind, agriculture may be considered as yet in its infancy; and I am of opinion, that in the next sixty years, a still greater advance will be made, than in any similar period which has passed."

"His Lordship, [Lord Braybrook, in the Stafford Walden meeting,] also exhorted agriculturists, to give to their children that sort of education, which was unknown when the elder agriculturists were young. Next to a conscience devoid of reproach, no blessing could be greater than that of possessing a well cultivated mind. The greater degree of instruction agriculturists gave to their children, the more happy they would make them—for the seeds of knowledge, properly sown, would come up and produce an hundred fold."

"This difficulty [said Mr. Binns, at the Preston meeting,] arises in a great measure, from the want of the same education amongst farmers that other classes enjoy. The scientific men, who make and recommend experiments, want practice; and the practical men, want science and education. For want of a knowledge in science, in cause and effect, farmers are not able to communicate their ideas and facts with the same facilities as others, nor properly to reason upon them. The merchants and manufacturers are congregated in towns, and have the advantage of libraries, lectures, newspapers, and a more ready communication with each other.—Even mechanics have great advantages over farmers. Let us then shake off the lethargy with which we are so *justly charged*, and be determined, as well as we can, to keep pace with the manufacturers.

"Other advantages would attend [agricultural] education. It would infuse an admiration of nature. This would not only refine the mind, and lead it to enjoy intellectual pleasures, before unthought of, but it would add to the blessings which surround us, unheeded and unenjoyed. It would increase the pleasures of social intercourse—it would teach humanity and kindness to all around us, and to the brute creation, and it would also increase our comforts in every shape. Is there any reason why the farmer should not take his rank in intellectual society? The youthful mind ought to be instructed in the principles of vegetation, the production of fruits and flowers, chemical agency, and the study of electricity, that mighty and mysterious power, which operates through earth and air in a manner very imperfectly understood. The advantages of science, are beautifully expressed by the Rev. Mr. Whewell, at the late meeting at New-Castle.—'The vast scheme of law, and order, and beauty, to which science introduces us, only lifts our thoughts to that great Being, in whom are the fountains of law and order, and who makes the earth his footstool, and the heavens his temple'"

"Agriculture was one of the most important, useful, and elegant sciences, [Mr. Gray, in the Lancashire meeting,] and took cognizance both of our subsistence and our comforts. The cause of the slow adoption of improvements by farmers, was the want of education among them. The manufacturer had opportunities of educating his children, which the farmer did not enjoy; and some system whereby farmers sons may receive a better education, would tend more than any thing else to relieve them from this reproach. They would then be better able to appreciate works of agricultural information, and would attend meetings of this sort.

"Let practical agriculturists, or their children, be educated [in the science which benefits their business,] then we should see agriculture make rapid strides. Let the children of farmers be also taught the elements of mechanics, chemistry, the nature of manures, plants and vegetation."

"It is as important to the country, that agriculture should be scientifically understood and studied, as that manufacturing science should progress. The mere culture of the land is nothing, except it is conducted on the best possible principles. To plough and manure—to sow and reap—to break up and lay down land—to breed and to rear stock, and to farm, and labor on a farm, merely as they who have passed away did, is no great merit. This is merely to exercise an imitative talent. The resources of the mind ought to be brought to the labor; and profiting not only by experience, but in learning by experiment, we may hope to see improvement progress in an equal ratio in agriculture as in mechanics; and the knowledge, that the stores of experimental philosophy affords, be applied to this, the most useful of all the arts, because it produces the raw material, on which the human race is fed and clothed. When the mere operative farmer knows the value of science, he will then see that it is the best auxiliary to the production of agricultural wealth; and learn the secret, why his better informed neighbor, who has devoted some attention to such pursuits, has beat him in the cause of enterprize."—*Chester Chronicle.*

The Importance of Pure Air,

To health, is in a manner unknown to the mass of mankind, and we believe it has been but partially known, even to the learned, until recently. And even where its importance has been known, due regard has not been had to secure its blessings. The purity of the air is destroyed by animal respiration, by putrifying animal and vegetable matters, by stagnant waters, and even, we believe, by becoming stagnant itself, under a warm temperature. Impure air exercises its deleterious influence upon the human system, in all damp or illy ventilated rooms—in the neighborhood of all putrifying animal and vegetable matters—of low marshy situations, and of stagnant waters—and in crowded close rooms, whether these rooms be jails, school-houses, work-shops, temples of religious worship, or temples of fashionable folly.

Gen. Mann, the secretary to the Massachusetts Board of Education, whose recent lectures in our city were listened to with the highest admiration, by thousands of hearers, has recently published a pamphlet, pointing out the defects in our school-houses, and suggesting correctives. Two of the prominent evils which are too common, are *bad location*, and the *want of ventilation*, or a due provision for securing to the pupils the constant advantages of pure air. As we shall make this report the subject of another article, we shall content ourself, for the present, with noticing such facts as go to illustrate the importance of *pure air* to health.

"It seems generally to have been forgotten," says our author, "that a room designed to accommodate fifty, one hundred, and, in some cases, two hundred persons, should be differently constructed from one intended for a common family of eight or ten only. In no one particular is this difference so essential as in regard to ventilation. There is no such immediate, indispensable necessary of life, as fresh air. A man may live for days, endure great hardships, and even perform great labors, without food, without drink, or without sleep; but deprive him of air for only one minute, and all power of thought is extinct; he becomes as incapable of any intellectual operation as a dead man, and in a few minutes more, he is gone beyond resuscitation. Nor is this all; but just in proportion as the stimulus of air is withheld, the whole system loses vigor. As the machinery in a water mill slackens when the head of water is drawn down; as a locomotive loses speed if the fire be not seasonably replenished; just so do muscle, nerve and faculty, faint and expire, if a sufficiency of vital air be not supplied to the lungs. * * * *

"The common or atmospheric air, consists mainly of two ingredients, one only of which is endued by the Creator with the power of sustaining animal life. The same part of the air supports life and sustains combustion; so that in wells or cellars, where a candle will go out, a man will die. The vital ingredient, which is called *oxygen*, constitutes only about twenty-one parts in a hundred of the air. The other principal ingredient, called *azote*, will not sustain life. This proportion is adapted, by omniscient wisdom, with perfect exactness, to the necessities of the world. Were there any material diminution of oxygen, other things remaining the same, every breathing thing would languish, and waste, and perish. Were there much more of it, it would stimulate the system, accelerating every bodily and mental operation, so that the most vigorous man would wear out in a few weeks or days. * * * About four parts of the twenty-one of vital air are destroyed at every breath; so that, if one were to breathe the same air four or five times over, he would substantially exhaust the life-giving principle in it, and his bodily functions would convulse for a moment and then stop. As the blood and the air meet each other in the lungs, not only is a part of the vital air destroyed, but a poisonous ingredient is generated. This poison constitutes about three parts in a hundred of the breath thrown out from the lungs. Nor is it a weak, slow poison; but one of fatal virulence and sudden action. If the poisonous parts be not regularly removed, (and they can be removed only by inhaling fresh air,) the blood absorbs them, and carries them back into the system. Just according to the quantity of poison forced back into the blood, follow the consequence of lassitude, faintness or death. The poisonous parts are called carbonic acid. They are heavier than the common air, and as the lungs throw them out at the lips, their tendency is to fall towards the ground or floor of a room, and if there were no currents of the air, they would do so.—But the other parts of the air, being warmed and rarified by the lungs, are lighter than common air, and the moment they pass from the lips, their tendency is to rise upwards towards the sky."

More strongly to demonstrate the deleterious influence of breathing foul air, Gen. Mann addressed to Dr. Woodward, of the Lunatic Hospital at Worcester, the following with other queries. A portion of Dr. W.'s reply follows.

"*Second query.*—What general effects will be produced upon the health of children, by stinting their supply of fresh air, through defects in ventilation?"

"The blood," says the doctor, in reply, "as it circulates through the vessels in our bodies, accumulates a deleterious principle called CARBON, which is a poison itself, and must be discharged frequently, or it becomes dangerous to life. In the process of respiration or breathing, this poisonous principle unites in the lungs with a proportion of the oxygen of the air, and forms *carbonic acid*, which is expelled from the lungs at each expiration. The proportion of oxygen in the air received into the lungs, is about twenty-one in the hundred: in the air expelled, about eighteen in the hundred; —the proportion of carbonic acid in the inhaled air is one part in the hundred, in the exhaled air about four parts in the hundred. By respiration, an adult person spoils, or renders unfit for this vital process, about one gallon of air in a minute. By this great consumption of pure air in a school-room, made tight and filled with scholars, it will be easily seen that the whole air will soon be rendered impure, and unfit for the purpose for which it is designed. If we continue to inhale this contaminated air, rendered constantly worse the longer we are confined in it, this process in the lungs will not be performed in a perfect manner; the carbon will not all escape from the blood, but will be circulated to the brain, and produce its deleterious effects upon that organ, to which it is a poison. If no opportunity be afforded for its regular escape, death will take place in a few minutes, as in strangulation by a cord, drowning and immersion in irrespirable air. The cause of death is the retention and circulation of this poisonous principle, in all these cases.

"If a smaller portion is allowed to circulate through the vessels than will prove fatal, it produces stupor, syncope, and other dangerous effects upon the brain and nerves. In still less quantity, it produces dullness, sleepiness, and incapacitates us for all mental efforts and physical activity. The dullness of a school, after having been long in session in a close room, and of a congregation, during a protracted religious service, are often attributable to this cause *mainly*, if not *solely*.—Both teacher and scholar, preacher and hearer, are often greatly affected in this way, without being at all sensible of the cause. Fifty scholars will very soon contaminate the air of a school-room at the rate of a gallon a minute.

"Suppose a school-room to be thirty feet square and nine feet high, it will contain 13,996,000 cubic inches of atmospheric air. According to Davy and Thompson, two accurate and scientific chemists, one individual respires and contaminates 6,500 cubic inches of air in a minute. Fifty scholars will respire 325,000 cubic inches in the same time. In about forty minutes, all the air of such a room will have become contaminated, if fresh supplies are not provided. The quantity of carbonic acid produced by the respiration of fifty scholars, will be about 750 cubic inches in an hour."

So far on air becoming vitiated and unfit for breathing, by reason of its having been taken upon the lungs. The extract which we make below, from the report of the English poor-law commissioners, shows other causes of the air becoming deleterious and poisonous to a fatal extent. Every individual has a deep interest in knowing the

"SOURCES OF FEVER.

"It is a matter of experience that, during the decomposition of dead or organic substances," says the report, "whether vegetable or animal, aided by heat and moisture, and other peculiarities of climate, a poison is generated, which, when in a state of high concentration, is capable of producing instantaneous death, by a single inspiration of the air in which it is diffused.

"Experience also shows that this poison, even when it is largely diluted by admixture with atmospheric air, and when, consequently, it is unable thus to prove suddenly fatal, is still the fruitful source of sickness and mortality, partly in proportion to its intensity, and partly in proportion to the length of time and the constancy with which the body remains exposed to it. Facts without number, long observed, such as the great amount of sickness and mortality in marshy districts, the fevers and dysenteries incident to armies on their encampment on certain localities, several hundred men being sometimes seized with disease in the course of a single night, and great numbers dying within twenty-four or thirty hours; the dreadful destruction which frequently took place in ship's crews, in ships in which cleanliness had been neglected, and especially in which the bilge water had been allowed to collect and putrify, sufficiently attested the presence, in certain situations, of deadly poison. But this poison was too subtle to be reduced to a tangible form. Even its existence was ascertainable only by its mortal influence upon the human body; and although the induction commonly made as to its origin, namely, that it is the product of putrifying vegetable and animal matter, appeared inevitable, seeing that its virulence is always in proportion to the quantity of vegetable and animal matters present, and to the perfect combination of circumstances favorable to their decomposition, still the opinion could only be regarded as an inference.

"But modern science has recently succeeded in making a most important step in the elucidation of this subject.

"It has now been demonstrated by direct experiment, that in certain situations in which the air is loaded with poisonous exhalations, the poisonous matter consists of vegetable and animal substance in a high state of putrescency. If a quantity of air in which such exhalations are present be collected, the vapor may be condensed by cold and other agents: a residuum is obtained, which on examination is found to be composed of vegetable or animal matter, in a state of high putrefaction. This matter constitutes a deadly poison. A minute quantity of this poison, applied to an animal previously in sound health, destroys life, with the most intense symptoms of malignant fever. If, for example, ten or twelve drops of a fluid containing this highly putrid matter, be injected into the jugular vein of a dog, the animal is seized with acute fever; the action of the heart is inordinately excited, the respiration becomes accelerated, the heat increased, the prostration of strength extreme, the muscular power so exhausted that the animal lies on the ground, wholly unable to stir, or to make the slightest effort; and after a short time it is actually seized with the black vomit, identical in the matter evacuated with that which is thrown up by a person laboring under the yellow fever. By varying the intensity and the dose of the poison thus obtained, it is possible to produce fever of almost any type, endowed with almost any degree of mortal power.

"It is proved further, that when this poison is diffused in the atmosphere, and is transported to the lungs in the inspired air, it enters directly into the blood, and produces various diseases, the nature of which is materially modified, according as the vegetable or the animal matter predominates in the poison. In the exhalations which arise from marshes, bogs, and other uncultivated and undrained places, vegetable matter predominates; such exhalations contain a poison which produces, principally, intermittent fever or ague, or remittent fever

"The exhalations which accumulate in close, ill-ventilated, crowded apartments, in the confined situations of densely populated cities, where no attention is paid to putrifying and excrementitious substances, consist chiefly of animal matter; such exhalations contain a poison which produces continued fever of the typhoid character. There are situations, as has been stated, in which inspiration of it is capable of producing instantaneous death; there are others, in which a few inspirations of it are capable of destroying life in from two to twelve hours; and there are others again, as in dirty and neglected ships, in damp, crowded and filthy jails, in the crowded wards of ill-ventilated hospitals, filled with persons laboring under malignant surgical diseases, and some forms of typhus fever in the crowded, filthy, close, unventilated, damp, undrained habitations of the poor, in which the poison generated, although not so immediately fatal, is still too potent to be breathed long, even by the most healthy and robust, without producing fever of a highly dangerous and mortal character.

"But it would be a most inadequate view of the pernicious agency of this poison, if it were restricted to the diseases commonly produced by its direct operation.—It is a matter of constant observation, that even when not present in sufficient intensity, to produce fever, by disturbing the function of some organ, or set of organs, and thereby weakening the general system, this poison acts as a powerful predisposing cause of some of the most common and fatal maladies to which the human body is subject.

"The deaths occasioned in this country by diseases of the digestive organs, for example, by inflammations of the air passages and lungs, and by consumption, form a large proportion of the annual mortality. No one who lives long in or near a malarian district, is ever for a single hour, free from some disease of the digestive organs. By the disorder of the digestive organs, the body is often so much enfeebled, that it is wholly incapable of resisting the frequent and sudden changes of temperature to which the climate is subject; the consequence is, that the person thus enfeebled, perishes by inflammation set up in some vital organ, and more especially in the air-passages and lungs, or by consumption, the consequence of that inflammation. If, then, as is commonly computed, of the total number of deaths that take place annually over the whole surface of the globe, nearly one-half is caused by fever in its different forms, to this number must be added the number who perish by the diseases caused by the indirect operation of this poison."

The preceding extracts will serve to explain in what way air becomes poisonous to health,—will account for the faintings that often take place in crowded close rooms, and the indisposition that not unfrequently follows the visiting such assemblies. They are full of instruction for the every day business of life; and although we have recently pointed to some of the precautions which these facts urge upon us, yet the importance of the subject to health, will justify our repeating them. They admonish us,

1. To make our school-houses more roomy,—to adapt them to perfect and frequent ventilation—to

preserve cleanliness in and about them—to give them healthy locations, remote from marsh air, with ample play grounds and shade trees, to repel or mitigate the heats of summer and the cold of winter.

2. To build our dwellings on dry healthy locations —not to obstruct a free circulation of air about them by high fences or out buildings, or let any species of dead animal matters accumulate about them to poison the atmosphere.

3. To ventilate well our sleeping rooms, which should not have stoves, except to expel dampness, nor should the doors be closed at night in private dwellings, of apartments where there are several inmates.

4. To take special care to permit no vegetable putrefaction to take place in the cellars under our dwellings—to have these so that a current of fresh air may be made to pass through them whenever the temperature of the atmosphere will permit—to have them dry, and cleaned and whitewashed as early in the spring as the season and circumstances will permit.

5. To have our cattle-yards, stables and pig-sties so far from our dwellings, as that we shall not be obliged to breathe the poisonous exhalations arising from them; and carefully to remove from these in the spring, and as often at other times as good health and good husbandry require, all the dung and putrefying matters of which they may become recipients.

6. As domestic animals are affected equally with ourselves, the same care, as to cleanliness and ventilation, should be extended to them—clean ventilated stables, dry sheds to protect from the weather, and well littered yards—and the dung should not be permitted to ferment in the yard faster than it can be removed and covered in the soil, for the hoed crops of the season. The exhalations from summer yarded dung, especially where the cattle-yard or hog pen is contiguous to the house, circumstances which ought never to occur, have a most deleterious influence upon health.

7. A regard to health, as well as a desire to increase the productiveness, and to improve the beauty, of our grounds, should induce us to clear up and drain marshes, swamps, and all lands which abound in stagnant waters, the certain source of deadly malaria. The large tract of country lying in the neighborhood of Rome, termed the Campania, was, in the times of Roman greatness, well drained, and was healthy and extremely populous. In modern times the draining has been neglected, the population have virtually disappeared, and the deadly malaria, generated by its marshes, is annually the terror and the destroyer of man and beast.

8. And lastly, we should avoid many of the evils of vitiated air, by a particular attention to personal cleanliness. A large portion of the food which we daily consume is thrown to the surface by insensible perspiration, where, unless aided in its escape by exercise in the open air, change of clothing, or frequent ablutions, it accumulates, obstructs the healthful offices of the skin, vitiates the air which we breathe, and induces disease. The odor given off by diseased persons, or those of dirty habits, and particularly by blacks, indicates the presence of those poisonous matters, which are ever obnoxious to health. Grown persons, according to Lavoissier, throw off an average of five pounds per day, of impure matter, through the skin, highly charged with poisonous properties; and if not habitually removed by habits of cleanliness, they must taint and poison the air we breathe.

The Mind and the Soil.

In cultivating the soil, we have our seed-time and our harvest-time; and we all very well know, that if the good seed is not deposited in good time, the harvest will be scanty, or will fail. We can reap only what we sow, unless it be the weeds and noxious plants which spring up spontaneously from our neglect. So it is with the mind. It has its seed-time and its harvest-time—its vernal season of youth, and its summer season of manhood. And the good seed we sow in the young mind, will as assuredly grow, and give its increase, as that which we deposite in the soil. Our crops tend to increase our wealth, and add to our animal enjoyments. The improvement of the mind not only tends to these desirable ends, by aiding the labor of the hands, but it tends to knowledge, to virtue, to happiness.

Do we estimate these things rightly, and give to each its relative value? Do we not graduate the wages of the laborer, who cultivates our soil, by the measure of good he can render us? And do we not graduate the wages of the teacher, who cultivates the minds of our children by a very different principle —by the small amount which his wants or his limited capacity compels him to take? Are we not apt to make merit the criterion of our choice in the cultivator of the soil, and the want of it the criterion of our choice in the cultivator of the mind? And yet, all must acknowledge, that qualification and excellence are as much more indispensable in the latter, than it is in the former, as mind is superior to matter—as a good man is superior to a good crop. Who would not feel a higher pride in rearng a family of intelligent, virtuous and useful children, than in rearing a fine beast, or in raising a great crop of corn? Let us try to mend in this matter—to get good laborers in the mental and moral, as well as in the vegetable field of culture. Then shall our children "rise up and bless us."

Agricultural Books for Common School Libraries.

Mr. Beebe, of Lima, inquires of us, what agricultural books are suitable for a common school library? We are glad the question has been asked us, but regret that we cannot answer it more satisfactorily to ourselves and to our correspondent. The demand for books upon agriculture has been so limited, that there has been but little inducement to write or publish them. The dependence of those who have wished to improve their practice in husbandry, has been principally upon British publications, not well adapted to our practice, however correct in the principles upon which good practice must be based—and upon the agricultural periodicals of our country. Yet, there are some valuable books upon agriculture, both American and foreign, which we *can* recommend; among which we will name Davy's Agricultural Chemistry, Chaptal's Chemistry applied to Agriculture, Sir John Sinclair's Code of Agriculture, Armstrong's Treatise on Agriculture, Ruffin on Calcareous Manures, Lorrain's Husbandry—and, if we may be excused for what to some may seem egotism, we would particularly recommend, as agricultural works for every common school library, the Cultivator and Genesee Farmer, of our own state, and some of the agricultural periodicals of other states, in a suitable bound form. We do not hesitate to say, that these periodicals furnish more useful matter for improvement in agriculture, and in rural and household economy, than almost any books that can be procured in the American market; with this further advantage, that they do not cost so much, by one-half or two-thirds, as the matter they contain would cost in any other form. They are records of the improvements of the day in every branch of husbandry, and of rural economy, adapted to the every day wants of an agricultural population. To speak of the Cultivator alone—in the last twelve months, it has received and published the communications, mostly upon practical husbandry, and by practical men, of more than two hundred correspondents. Every farmer will acquire some useful hints, and improve his practice, from the better example of a neighbor. This example adds to his stock of useful knowledge. How greatly does it add to these advantages, when, instead of the improvements of one, he can profit from the improvements of two hundred good farmers.

There are several minor works upon agriculture, as Fessenden's Practical Farmer, Budd's complete Practical Farmer, Taylor's Farmers' School-book, &c., which are principally made up of extracts from agricultural books and periodicals. But most of the books we have named are scarce in market. The editions were limited, in consequence of the little demand for works of this kind. The agricultural books adapted to an American Common School Library, *are yet to be written.*

A common school library should contain something upon gardening—a branch of rural economy, that has hitherto received far less attention than its importance demands. Good gardens, among a rural population, are the highest marks of social refinement. They exert a benign influence upon our rougher passions, and the grosser appetites, and enhance the charms and enjoyments of home. We may name Bridgman's, Fessenden's and Wilson's.

We want in these libraries, also, plain treatises upon silk culture, a business of unquestionable profit, as a household employment—and a proficiency in which may be attained by a little practice, with the aid of printed directions. We name Whitmarsh, Comstock, and Roberts. The principles of mechanics are all important to a rural population. To apprehend them, and their mutual relations, says Babbage, is within the power of almost every person possessing a tolerable education. A knowledge of these principles is valuable to the farmer, and mechanic, and manufacturer, in the construction and management of the implements and machines which add to human power, and economize time. Of works of this kind, we understand two are preparing by competent gentlemen of this state, and will be published the current year.

We should also have in these libraries, some works calculated to make our sons early acquainted with the constitution and laws of the land—with their duties as citizens and freemen—and to make our daughters good housewives, and good economists. "The Citizen's Manual," by Judge Concklin, is an invaluable work for the first of these purposes. Neither young nor old can peruse it without benefit—without feeling a new interest in the preservation of social order, and new obligations to qualify themselves for the high political and social duties of freemen. Upon household and domestic duties and accomplishments, we have several valuable works, from American ladies, among whom are Mrs. Hale, Mrs. Sigourney, &c.

Utile dulci—"the useful, with that which is agreeable," has long been a favorite quotation, and the sentiment is one which we respect. The *useful* should have precedence of the *agreeable.* We should teach our youth how to *earn* wealth, before we instruct them in the fashion of *spending* it—we should build the house, before we expend our means for its furniture and embellishments. Nine-tenths of those, who are to get benefit from common school libraries, are destined to obtain a livelihood by manual labor,—and our first object should be to render their labors inviting and respectable, by affording them the opportunity of rendering them intelligent and profitable. We speak with confidence, when we say, that agricultural labor would be rendered far more profitable, at least one-third, in the coming, if not in the present generation, by the facilities to improvement which might be afforded through common school libraries; and we have no doubt, that other branches of productive labor might be equally benefitted. We estimate the value of our present agricultural products at ninety millions of dollars per annum. On our assumption, endorsed by our chief magistrate, that the value of this product might be increased one-third, or thirty millions of dollars, by proper instruction and encouragement—how paltry in comparison, is the small sum asked for from the legislature, to furnish this encouragement and instruction? It is better to give our sons a *useful* education, without fortune, than to give them *fortune* without a useful education. Men wed habits, before they wed wives, and generally cling to them longer in life.

We spread our nets too broad.

The great misfortune in our country is, that when a good thing is started, there are too many who want to share in its honors and its profits; and hence what would be very useful and profitable to a limited extent, is, by being divided, and subdivided, as respects the patronage of the public, rendered useless to the projector, and of very little benefit to the public.

We will apply our remark, first, to our colleges, our highest schools of learning. A certain number of these, by concentrating the public patronage, and the bounty of government, would be able to confer the highest qualifications for usefulness, and the highest honors, upon the pupils under their charge. But when we divide among two or three, or a half a dozen, the public bounty and the patronage which is necessary to render one useful, we overdo the business, and in a measure thwart our object of high intellectual improvement. We adopt the foolish policy of the farmer, who expends his labor upon three hundred acres, when by jucicious management, he might get the same produce from one hundred acres, and save the expense of two-thirds of the land and two-thirds of his labor.

Next, our academies. Every cluster of houses that is denominated a village is ambitious of having an academy, forgetting that it requires an outlay of some thousand dollars in the outset, to start one respectably, and an income, annually, in tuition fees, or from other sources, of two thousand dollars more, to maintain it usefully. The consequence is, that very few offer, for any length of time, so good advantages as a private school. Were two-thirds discontinued, or converted into industrial schools, to teach hand-work as well as head-work, the remaining third would be far better sustained, and be far more useful. The worst place to educate a boy, so far as depends on the advantages of the school, is his native village, where he is wont to lean on parental support and to remain a mere succor. Send him among strangers, and he will learn to *go alone,* and to depend, for knowledge and character, upon his personal application and good conduct. Under shelter of the parent tree, the succor will always be a succor—soft, porous and dependent; but early removed, it strikes its roots vigorously into the soil, towers aloft, and soon ranks with its parent, in hardiness, beauty and usefulness.

Then our canals, rail-roads, and turnpikes, come in for a like competition for public favor, and involve a like useless expenditure. By their unreasonable multiplication, individuals, and districts, may be gratified, but the public are seldom benefitted to the extent of the outlay; but this matters little to the projectors, provided the state can be induced to lend its credit for their completion, and ultimately to assume their ownership.

We are not sure that our agricultural periodicals, useful as they are to the community, are not multiplying too fast, both for the benefit of their conductors and of the public at large. It is not their number, but their quality, that confers value; and their price must be graduated in a measure by the extent of their circulation. Three of these periodicals are now issued from Boston; three are published in Ohio, and three in Tennessee. *We* are not disposed to complain; but we verily think, that was the talent which conducts, and the patronage which supports them, somewhat more concentrated, in the cases we have noted, it would be better both for the proprietors and the patrons.

In horticulture, we have now but one periodical, the Magazine of Horticulture, published at Boston by C. M. Hovey. We hope to see this liberally patronized, and well established in usefulness, ere the patronage which it deserves, and which can alone render it truly useful, is divided among half a dozen rival works.

Yet there is one business in which no evil is likely to arise from competition and rivalship. The more that embark in this, and the more successful they become in outdoing their neighbors, the better for them and the better for the country. We mean the business of practical agriculture—a business calculated, above all other employments, to make men "healthy, wealthy and wise," as poor Richard says. Here is ample scope for competition, for rivalship and for enterprise, without interfering with the prosperity of our neighbors, or compromitting our character, or, what freemen should hold most dear, our independence. A man who can, under the favor of heaven, supply his own wants by his own industry, should never consent to become the venal tool of others.

Forcing Rhubarb.

In our December number, we stated Mr. Knight's mode of forcing rhubarb; and at the same time we directed our gardener to fill a half barrel with roots and earth, and place it in the cellar. About the first of February the tub was taken from the cellar and placed in the back part of a basement kitchen, and covered over by another tub to exclude the light. On the first of March the tub was filled with fine blanched stocks of rhubarb, from twelve to eighteen inches in length, upon the top of which the leaf was just developing. The rhubarb not only makes a superior pie, but is said, by medical men, to make a very healthful one.

North Anna Agricultural Association.

We invite the attention of the reader to the preamble and regulations of this association, under correspondence. It is a mutual benefit association, calculated to add to the knowledge, and wealth, and good feelings of all its members, without impairing the good qualities or the wealth of any one. The monthly meetings will resemble the literary *converzasiones* of Paris, the meetings of scientific men in Britain, and the weekly agricultural *converzasiones* of Prof. Colman, which are now being held in the capital of New-England—where men come together not merely to benefit themselves, but to benefit their country, with the fruits of their knowledge and experience.

The Short-Horned fever in Kentucky

We are admonished by our worthy cotemporary of the Franklin (Ky.) Farmer, that we are no doctor, and that this fever has not yet reached its crisis in Kentucky. We admit that we have been better advised since we hazarded our opinion; though we are not yet exactly prepared to retract it wholly. Kentucky is undoubtedly well adapted for grazing, both on account of the richness of its pastures and its interior location. The Short-Horns find there a home—the climate is much more congenial to them than that of latitude 43—and they grow larger and do better there than they do here—and yet gold may be bought too dear. At all events, we hope, if our life is spared, to accept the kind invitation of friend Stephenson, and to be able to judge more understandingly in the matter. In the meantime we commend, without stint, the spirit of improvement which animates the editor of the Farmer and his respectable correspondents.

What is Education?

"It is," say the schoolmen, "the training of the whole man, the development and proper exercise of all his powers—the cultivation of his physical, intellectual, moral and religious nature"—and we would add—that although every thing necessary may be here implied, all is not clearly expressed. Education is not complete till the pupil is trained to some useful employment, by which he can earn an honest livelihood—and this training, too, if to an agricultural or mechanical employment, will give the best development to his physical and moral powers, and afford the strongest guarantee for their active exercise. Nothing tends more to promote moral culture, than a consciousness that we *can*, and a determination that we *will*, provide for ourselves, by our own honest industry. Without some fixed employment, while the body and mind are ductile, and capable of receiving lasting impressions of usefulness, both the physical and moral powers are apt to relapse, however well trained, the first for want of due exercise, and the latter for want of bread. Education should not only develop the bodily and mental powers, but should teach their proper and useful employment.

New Species of Silk Worms.

In the province of Assam, in Asia, which has recently fallen under the jurisdiction of British power, among a variety of hitherto unknown productions, there has been found a dozen species of silk-worms, which produce materials for valuable fabrics. One of these is the muga worm, which feeds on the foliage of a variety of trees, and is never reared in the house. The female deposites its eggs on wisps of grass, which are collected, and when wanted to be hatched, the wisps are exposed to the sun about ten days, when the worms begin to show themselves.—They are then hung up in a tree which has been selected for the purpose, and the worms find their way to the foliage. If a tree is stripped of its leaves, the worms are removed to another, by means of bamboo dishes, fastened to long poles. They are prevented coming to the ground by plantain leaves being tied round the body of the tree, over which they cannot crawl. They feed about thirty days, and when ready to wind, descend to the plantain leaves, where they are gathered, placed among dry leaves, where they form cocoons. The cocoons are about two inches long, and of proportionable thickness. They are not reeled in one continuous thread, like common silk, but spun, like cotton or worsted, and of course the product is a thicker and harsher thread. The silk is wove into cloth, for scarfs, turbans, sashes, &c. In that warm climate, the insect produces five crops in a year.

The arinda worm is reared entirely under cover. It has been known to have perfected twelve broods in a year. The silk, though coarse, is warm and durable, and is worn by the common classes. More than 80,000 lbs. of arinda, and 50,000 lbs. of the muga silk, are annually produced in Assam. The cloth is said to be of incredible durability; the life of one person being seldom sufficient to wear out a garment made of it. One other sort of these silk worms produces a beautiful thread of great lustre; and a fourth sort is of very large size, the moths measuring ten inches from wing to wing.

The Grain-Worm.

It will be seen, by the letter from Mr. Gaylord, under correspondence, that we were right in our conjectures, that the grain-worm of the east, and the grain-worm of the west, are not identical, that they belong to different genus of insects, and are altogether different in their appearance and habits. We will however indulge in another conjecture, viz. that the grain-worm of the east (*Cecydomia tritici*) is partially in the west, as far at least as Ontario, and that it has there committed ravages upon the wheat crop, *without having attracted notice.* The complaint there has been general, that the product has fallen short of the grower's expectation, to a greater extent than could be accounted for by the apparent depredations of the *Phalæra* of Mr. Gaylord. The true grain-worm, of which we have so often spoken, is seldom if ever found in the wheat head at harvesting, or in the barn. It falls to the ground before harvest. If when the grain is yet in milk, an upright head be selected, and the thumb and finger passed along it, it will be perceived that there is a partial, and sometimes a total deficiency of kernels. On opening the sheath of these abortions, or empty grain cells, the worm will be found in the envelope, sometimes to the number of a dozen. They either destroy the entire germ, or, if the kernel has partially formed when they begin their work, it has a very shrivelled and worthless appearance, having been evidently deprived of the nourishment destined to bring it to perfection.

Whitmarsh's Silk Manual.

"*Eight years experience and observation in the culture of the mulberry tree, and in the care of the silk-worm.*" *&c.* is the title of a duodecimo of 156 pages, just published by S. Whitmarsh, of Northampton. There is probably no individual in the United States, who has had a better opportunity of noticing all the varieties of the mulberry, and the various processes in the silk business, in France and Italy as well as in America, than the writer of this little work. This, taken in connexion with his eight years experience in the business, must have qualified Mr. W. for the task he professes to have undertaken, that of furnishing to the farming interest plain and simple instructions, adapted to our country, for the culture of the mulberry and the management of the silk worm. Mr. Whitmarsh concurs with us in the opinion, that this business belongs particularly to the farmer and planter; and that in their hands it will ultimately become one of great magnitude and wealth to the Union. And we concur with him in recommending farmers to plant the mulberry, in the full assurance that they will be wanted—if not by the owner, by some neighbor who will find an interest in buying the foliage.

It is not our intention to review this work. We propose merely to state some prominent facts, which it asserts, and to refer to the book for the reasons, and for general directions.

No particular species of the mulberry is preferred. Too much consequence has been attached to the size of the leaf; and he seems inclined to prefer the white fruited varieties. Mr. W. is in error in classing the black mulberry among our indigenous varieties. The black (Nigra of botanists) is a native of Europe, and more sensitive to the cold of our winters than the multicaulis. He recommends poor dry soils, where the leaves will be richer, and the wood mature better, than on rich or wet grounds. The leaves should be stripped from trees but once a year. Several crops of worms may be fed in a season, but not from the same trees. This is undoubtedly correct. The leaves are improved by the age of the tree. No kind of mulberry under cultivation can be produced from seed; that is, no seed can be depended on to produce trees like its parent. Of this fact we should require more proof before we should be disposed to give it our unqualified approbation; but if true, it will soon explode the venders of seed of the *genuine* Canton, multicaulis, &c. at four and five dollars the paper. We are not inclined to think it correct in regard to the white or Brussa, the seedlings of which we think bear a uniform resemblance, in their wood and foliage, to the parents. Where both parents are of the same species, the progeny, in the vegetable as well as the animal, are not likely to take a new form. We commend the work to the silk culturist.

"None so Blind as those who won't See."

That man who won't profit in his farming operations, by the palpably better practice of his neighbor, is branded, by common consent, an idler or a dunce; and his case may be considered one of hopeless obstinacy. He virtually scouts at the means which Providence has placed within his reach for the great purpose of his being—the improving his condition and benefitting others. He is like the noxious plant, which encumbers the earth, to benefit no one—except to exhibit, in strong colours, the contrast which exists between the useless and the useful—between industry and indolence—between the good and the bad, in human affairs. He who aids, in any honest way, to multiply the comforts of life, to enlarge the sphere of useful knowledge, and to elevate the character of society—has at least the consolation—and it can only be acquired from practice—that he has used those faculties, which Providence has given him above the brute, for the purposes for which they were intended—the good of mankind. While he who will not improve and employ the high faculties of his nature to advance human happiness, may be likened to the turtle, which delights in mud and water, and cares only for itself, or to the carnivorous beast, which feeds and fattens upon the life-blood of the brute inhabitants of the forest.

We have been led into this train of rather serious reflections by the perusal of a letter before us, from Mr. W. Bache, which, although stating nothing but what is common in every district, gives the objections of his neighbors against endeavoring to improve in their business through the example of those who excel them in practice.

"If you will publish a work on law, physic or divinity," says our correspondent, "I will undertake to get farmers to subscribe to it, because those are subjects well calculated to be treated on in books, and farmers would think they might learn from them something which they did not know before; but to instruct *them* in the art of farming, who never learnt any thing else from their infancy, nor their fathers before them, how ridiculous! There are others, however, that offer reasons rather more plausible. These improvements, say they, are very fine, to be sure; and if I lived in an old settled country, I should be very fond of taking such papers; but what good will they do us? They are not calculated for a new settled country. We have to farm as we can. We already know a great deal more than we can practice. Their improved ploughs and cultivators would make but poor work among our stumps. It would'nt be very easy draining land through roots. Why tantalize us with the wonderful effects of bone dust and lime? Our ground is strewed over with the one, without any possibility of getting them ground, and of the other there is none within fifty miles, and who can afford to put lime on land, every bushel of which will cost him fifty cents. It is true, I see some things in that Cultivator you lent me, that if I had the money I would have, or do; but we han't the capital necessary to do these things, and must wait till we have. There are others, however who like to know what is going on in the world, in their own profession, and feel encouraged to hope, by what others are actively doing, that some time or other they may be able to do the same, or better, themselves. Of such characters, we have a few even in Wellsborough, and I have the pleasure of sending you the names of the following nine, as subscribers," &c

☞ James Wickham, of South Westerlo, Albany county, is desirous to hear from his brothers and sister, Ebenezer Wickham, Benjamin Wickham and Abigail Wickham.

No one tastes so good Fruits as he who raises them.

This is particularly true as regards the small fruits of summer. The black mulberry, it is stated in the Encyclopœdia Americana, is "in perfection only a few moments, and that at the time when it can be detached from the tree by a slight shaking of the branches." "All the fruits," says Dr. Alcott, "but more particularly the berries, are more or less subject to the same law." The perfection of the strawberry and raspberry lasts but an hour or two; and even the pea, bean and Indian corn, lose much of their freshness and flavor by being plucked the day before they are used. Those who raise fruits, therefore, may pluck and eat them when they are at perfect maturity, when they are most grateful to the palate, and most conducive to health. Those who buy them, on the contrary, must buy those that are prematurely gathered, or which have passed their best state, and are in the incipient process of decay. In general both of these objections lie against summer fruits which are sold in the market—they are gathered before they are ripe, and they are in the progress of decay. How important is it, therefore, that the lovers of good fruit should take care to have it in perfection, by selecting and cultivating the choice varieties, when it can be done at trifling expense.

"The juices of all green fruits," says Dr. Alcott, "are very different from those of ripe ones. Their *acids* are less wholesome than after they are changed by the action of the sun in ripening; nor does the addition of saccharine substances in preparing them, at all change their real nature. They are still there; they are only concealed. The oxalic acid is still oxalic acid, cook green fruits as you will. No culinary process, I repeat it, can be substituted for, or produce the effect of solar action. The Creator, in many instances, by means of the sun, performs the most perfect culinary processes; and nature is often the best kitchen and cook."

The use of ripe fruits is admirably adapted to allay the feverish irritations of the stomach and bowels at the seasons when they severally come to maturity; but unripe fruits, or those in the incipient stages of decay, are calculated to increase these excitements, and to generate disease. Fruits should always become ripe in their own natural way, and eaten when they are in their highest perfection.

Bone Manure.

Since bone manure has become accessible to a considerable portion of the farming community, by the erection of bone mills at Albany, Waterford, New-York, Boston, and other places—and is likely to come into more extensive use, as its value is better appreciated—we propose to give some account of its fertilizing properties, of the soils and crops which it is calculated most to benefit, of its mode of application, the quantity applied to the acre, &c. In doing this, we shall draw our facts principally from the report of the committee of the Doncaster Agricultural Association, a society which has rendered eminent service to the agricultural community, in different departments of husbandry, by its investigations and reports.

With a view of collecting facts to form the basis of their report, the committee addressed seventeen queries to the most intelligent farmers of the country, embracing men of science, and asking answers to the interrogatories in regard to this manure. Forty-nine answers were returned. From these the committtee made out their report; and it is the substance of this report we are about to give.

Bone manure had been used, by those to whom the queries were addressed, for an average period of twenty years. "Our correpondents," says the report, "with only two exceptions, all concur in stating it to be a highly valuable manure, and on light dry soils superior to farm-yard dung and all other manures." In copying the language of one of them in relation to dry sandy soils, we express the opinions repeated in the far greater number. "I consider bone tillage one of the most useful manures which have ever been discovered for the farmer's benefit. The lightness of carriage, its suitableness for the drill, and its general fertilizing properties, render it peculiarly valuable in those parts where distance from towns renders it impossible to procure manure of a heavier and more bulky description. The use of the bones diminishes labor at a season of the year too when time is of the first importance; for one wagon load of a hundred and twenty bushels of small drill bones, is equal to forty or fifty cart loads of field manure."

"Upon very thin sand land," say the committee, "its value is not to be estimated; it is not only found to benefit the particular crop to which it is applied, but extends through the whole course of crops, and even in the succeeding course, its effects are visible in the improved quality of the land, and the efficiency of a smaller quantity than would have first ensured a crop." Numerous facts are here cited in proof of this declaration of the committee. Where, for instance, in a district of many thousand acres, turnips would produce only tops, and those very small, the use of bones alone has increased the turnip crop in some cases ten, and in few cases less than five fold; and all the succeeding crops of grain and grass were amazingly increased.

On light loams the bones were found preferable to yard dung—provided they are dry—for the bones do not seem to benefit at all upon wet soils.

On heavy loams and clays the experiments were unfavorable; and the committee infer, that clay soils are in general too moist to receive any considerable benefit from bone manure.

Upon peat soils, thoroughly drained, the advantages of bone manure were very striking. Fifteen to twenty bushels per acre were found to surpass, very far, the ordinary dressing of farm yard dung, and even lime and pigeons' dung.

Upon gravels, the opinions of its efficacy are contradictory. Upon wet ones it will not succeed.

As to its durability. Three acres were boned with one hundred and fifty bushels per acre by mistake. Fourteen years after, the land had not forgotten it, but was nearly half as good again as the other part, farmed precisely in the same way, with the exception of the one dressing of bones.

To the question, do you continue to use bones? not one in the forty-nine returned an answer in the negative. Their use was rapidly increasing.

Upon grass, either for meadow or pasture, their effect was favorable, the herbage being improved in quality and quantity. Six hundred bushels were spread upon twenty-four acres of a dairy farm, of dry sandy gravel, which had been laid down ten years. The effect was to produce double the butter from the cows depastured upon it, to those which were fed upon like pasture not boned.

The general application of bone dust in England is to the turnip crop, one of the most important in British husbandry; and the opinions as to the best mode of applying it, whether in drills or broadcast, are various, though the former opinion rather prevails.

As to the size of the bones, the opinion is in favor of half inch bones. Mr. Burk states—"If I were to till for early profit, I would use bones powdered as small as saw-dust: If I wished to keep my land in good heart, I would use principally half inch bones, and in breaking these I should prefer some considerably larger." "By using bones of a large size, with dust in them," says another correspondent, "I think I have sufficient of the small particles to set the crop forward, and sufficient of the large particles left to maintain the land in good condition for the last crop" in the course.

In regard to the quantity to be applied to an acre, although the committee admit that the average of the returns is thirty-nine bushels, they nevertheless recommend, as a sufficient dressing, twenty-five bushels of the small size, and forty bushels of the half inch, giving to the poorer lands a greater, and to the richer ones a smaller quantity.

Some of the correspondents prefer raw or fresh bones, and some those which have been boiled, and the glue and oil extracted.

Without going into further detail, we shall close our notice of the report, by copying a summary of the deductions which the committee draw from the facts they collected. They are as follows:—

> "On dry sands, limestone, chalk, light loams, and peat, bones are very valuable manure
>
> They may be laid on grass with good effect.
>
> On arable lands, they may be laid on fallow for turnips, or used for any of the subsequent crops.
>
> That the best method of using them where broadcast, is previously to mix them up with earth, dung or other manures, and let them lie to ferment.
>
> That if used alone, they may be either drilled with the seed or sown broadcast.
>
> That bones which have undergone the process of fermentation, are decidedly superior to those which have not done so.
>
> That the quantity should be about twenty-five bushels of dust, or forty bushels of large, increasing the quantity if the land be impoverished.
>
> That upon clays and heavy loams, it does not yet appear that bones will answer.

From the foregoing data, the farmer will be able to judge how far bone manure is adapted to his soil; and from estimating its cost and transportation, he can calculate the economy of purchasing and applying it. In the report before us it is computed to be cheaper at 2*s.* (44 cents) per bushel for manuring, than yard dung, at 10*s.* ($2.22) the load, the price the latter is stated at in Britain. The price at the mills in this state is $14 to $16 per ton, which would bring it to more than 40 cents a bushel. So that to manure an acre with twenty-five bushels would cost about $10.75, besides transportation and spreading. This dressing would be equal to that afforded by twenty common loads of manure, which ought to be estimated to be worth 50 cents a load, besides the expense of hauling it out and spreading it. It would therefore seem to be cheaper than stable manure; and at all events it would afford a valuable auxiliary where manure is scarce, or has to be brought from a distance.

Bone dust is for sale at the glue factory of T. Coulson & Son, on the Schenectady turnpike, Albany, and by R. Burt, Waterford.

"The Memorial,

"*Devoted to the reduction of costs attending legal proceedings in the collection of debts,*" is the title of a respectable sheet, which we have received from Seneca Falls, A. Bascom, editor. Its object is to make known the defects of our laws, and the impositions which are practised under them, in regard to the legal collection of debts.

We allow to the legal profession all the innate virtues and good feelings which are common to the other classes of society. But we have made them the peculiar subjects of temptation; and have environed them, by our own acts, with motives and with power, to become a privileged class, like the aristocracy of Europe. We make them our law-makers, our law-expounders, and virtually judges of the compensation which they shall receive. We have made the profession of law the avenue to all the offices of honor and emolument, by the long practice of selecting from the profession most of our executive and judicial officers, and a great portion of our representatives in the national and state legislatures. We have assisted to qualify them for these stations, by appropriating two millions of dollars of the public money to colleges and academies, in aid of their education. But we have not expended any portion of the public money to qualify the farmer and mechanic for like duties.—Hence they *are* a privileged class; and, like all other privileged classes, exercise the powers which are conferred upon them. Is it a wonder, therefore, that the profession should be crowded with candidates, of all sorts, for public favor? Is it unnatural that, encouraged by public bounty and public patronage, and possessing the power to help themselves to what they wish, that *all* of the profession should not possess sufficient virtue and integrity to resist the desire to grow rich upon the labors of the middling class? We only wonder that there are so many honest lawyers as we find.

From a cursory examination of the *Memorial*, we think its tendency is useful, its motives patriotic, and its means mild, liberal and just; and we recommend it to public patronage.

Among other matters, it is shown pretty satisfactorily, in the Memorial, that where the costs on collecting a note are now *fifty dollars*, besides sheriff's fees, they might be reduced, without prejudice to the plaintiff, to *fifty cents*, besides sheriff's fees, and yet afford a fair equivalent for *services rendered.* The expense and delays of chancery proceedings form a far greater cause of complaint than the courts of justice; so much so, that a man who has $500 due him on a mortgage, had better sacrifice the debt, than attempt to realize it by equity proceedings—if a lawyer takes an interest in keeping him out of it.

We have had some experience in these matters. We became a disinterested endorser for a friend, to the amount of seven or eight thousand dollars, for which we received a mortgage upon real property as security. Our friend failed, and left us to take up the paper. We commenced a foreclosure of the mortgage in chancery. Although we believe our counsel has done his duty, the cause has been pending five or six years, and is likely to out-live us—and for no other reason that we can see, than to accumulate costs—and to secure to a lawyer the possession of the property upon a nominal rent.

Durham Cattle.

Several individuals of this esteemed breed have recently been bought up in this neighborhood, by a gentleman from Kentucky. The purchaser remarked to us, that the climate of Kentucky appears to be much more favorable to this breed than the climate of our latitude.

Agricultural Items.

The Penobscot Agricultural Society awarded premiums in October, on the following products of an acre, viz:—42 bushels of wheat, 87½ bushels ears of corn, 84 bushels of oats, weighing 34 lbs. per bushel, carrots 600 bushels, &c.

Fellenbergh, pointing to three hundred pupils belonging to his school, said to Prof. Griscom, when visiting the school at Hoffwyl—"Do you see those young men? They are all teachers. If I do but pursue the right course in education, I shall revolutionize Switzerland." The worthy patriot alluded to the agriculture, the schools, and the intellectual and moral character of Switzerland. And who would not like to see such a revolution here? Such a revolution we want, and such we might have, if we would adopt Fellenbergh's plan.

The difference between a working man and a teaching man.—The laborer asks the farmer, "Do you want to hire a hand, Sir?" "Yes, if he suits me. *What can you do?* Can you mow? Can you cradle? Can you drive a team? Can you thrash?" The teacher asks him, "Does your district want to hire a teacher?" "Yes, *how much a month do you ask?*" In the first case, animal power and tact constitute the criterion of merit; in the second, the low price at which the applicant holds his mental qualifications. If the hireling does his work, no matter whether the children learn any thing useful or not.

Sweet Potatoes, have been kept till May, packed in a box of dry earth in autumn, placed in a position free from frost, and *exposed to the influence of smoke.*

Efficacy of Bone Manure.—Horace Callimore, states, in the *Plymouth Rock*, that he expended twelve bushels of bone manure, when brought into an incipient state of fermentation, upon his mangold wurzel and ruta baga crop, scattering it in every other drill—a handful in three feet; and that on gathering the crop, he found that he had four bushels of mangold wurzel, and two bushels of ruta baga—(both being alternated in the same row) in each row where the bone manure was applied, and but one bushel of each, in the rows where it was not applied, although the whole was manured with a compost—thus shewing an increase of two-thirds where the bone dust was applied.

Elastic Forks.—We accede to the proposition of O. Everett, of Sherburne, Mass.

Davis' genuine Ploughs—are manufactured and sold by Davis & King, Georgetown, D. C. dealers in produce, garden-seeds, &c. and agents for the Cultivator.

Morus Multicaulis trees and cuttings, sold by Joseph Bloodgood, Cultivator agent, Flushing, L. I., who sells also the China tree corn.

Italian Wheat.—Fifty bushels of pure seed have been imported, and are for sale, by J. Hathaway, P. M. Rome, Oneida county.

Notices of Correspondence.

Correction.—We quoted Mr. Whitmarsh, in one of our late numbers, as saying, that the "Alpine mulberry was universally raised in France and Italy." We are advised by Mr. Whitmarsh, that he was misunderstood by the gentleman who reported his remarks—that he said no such thing. His expression was, that "the better varieties of the white mulberry were grafted and budded universally in France and Italy, and that such a system would not answer for this country."

Our back volumes, in relation to which we are enquired of by S. Armstrong, of Bethlehem, Ia. may be had bound of our agents at New-York, Philadelphia, Baltimore, &c. see agents. Mr. A. will find answers to his inquiries in back vols. Timothy is best sown in September with winter grain, and we think, though we do not know, that blue grass is best sown at the same season.

Lice upon Cattle.—A. Higgins, of Smokey Hollow, asks for a prescription for destroying lice upon cattle. Boil the stems or leaves of tobacco in water, and apply the liquid, when cold, along the back, shoulders and neck of the animal, once, twice or thrice. Or, what is said to be equally efficacious, give a little flour of sulphur, once or twice a week, with salt, which the animal will eat kindly.

Berkshire Pigs—We have several inquiries in relation to Berkshire pigs. We refer, for answers, to the advertisements accompanying our Feb. No.

Boynton's Straw Cutter, we have neither tried nor seen. We refer J. A. D. to our advertising sheet for February.

Rohan Potatoes—We are obliged to repeat, that we have had none of these on hand since October, to part with. We dare hardly name the current price, as it is constantly advancing, and is now $6 the bushel.—See advertisements in our February sheet.

Farming in Middle Tennessee—John Brown writes from Columbia, Ten. as follows: "In Middle Tennessee our climate is very fine, our soil exceedingly productive, but our husbandry is in a most lamentable condition. From the intrinsic merit of the Cultivator, and the practical information offered to its readers, our agricultural labors must be greatly improved. Middle Tennessee is well adapted to the production of grain, roots and grass, of almost every variety. Heretofore we have been principally engaged in the culture of cotton, a misapplication of labor and capital, owing to our climate being too cold, and our soil too rich, for the profitable cultivation of that article. But the error is rapidly curing itself. I have the Cultivator from the beginning, and ten times its cost would not take it from me."

TRANSPLANTING EVERGREENS.

Stephen Earle, of Leicester, Mass. asks us the following questions.

1. "Which is the best time, spring or fall, to set out spruce and pine trees?
2. "Is it a good practice to mix barn-yard manure with the dirt that is put about the roots?
3. "Is it a good plan to water the trees occasionally if the season is dry?"

Our answers are, that the *best* time to transplant the spruce and pine, though they may be transplanted at any time, is the last of May or first of June, *after the plants have begun to grow*, or during any of the periods of active growth, if due precautions are taken to counteract evaporation, or to prevent the exhaustion of moisture in the soil. Barn-yard dung should *not* be mixed with dirt about the roots—rich surface mould is best. Water may be given to keep the ground moist, but not too wet. A bucket or more of water may be thrown into the hole in the process of transplanting—and the surface, after the tree is planted, should be covered with coarse litter, to prevent evaporation. Mr. Earle will find our reasons for this practice, and an account of our success in it, in the back volumes of the Cultivator.

Native Mulberry—A Fishkill correspondent inquires if the native black and red mulberry can be propagated by layers and cuttings? We have no native black. Without having had practical knowledge, we may venture to say that the native red can be propagated by layers, and we think by cuttings. Quince cuttings may be made at any time after the fall of the leaf and before the buds swell much in the spring. We think the best mode is to cut in the fall, and bury the shoots till spring.

One of our correspondents writes as follows—"Some of your correspondents seem to think, that there are none benefitted by the Cultivator but those who read it. But I am satisfied there are many who have never seen it have profitted by the information which it contains, through the influence and example of those who do read it. And as this knowledge comes to them in a manner that does not interfere with their prejudices, I have no doubt it is preparing the way for them hereafter, to be still more benefitted, by inducing many of them to turn their attention to books and papers that treat of agriculture."

Botsford's Thrashing Machine, is inquired for by several correspondents. Our readers are in possession of all the information we have in relation to it. We have seen a model, but have not seen the machine; nor can we give directions further than we have published.—Mr. Joseph P. Plummer, of Richmond, Ia. thinks, judging from the price probably, that they would just suit his country. ☞ Mr. P. had better grow beets upon his hog pasture, if it is moist, or inclined to clay.

Preparing Seed Corn—Edmund Wells, of Harmony, prepares his seed corn as follows: for half a bushel of seed, he dissolves nitre, or salt petre, in water, till it will bear an egg; makes the water about blood warm, and steeps his seed in it twelve hours. He then takes it from the tub, and pours upon it a mixture of 3 gills of tar, one gill of oil, half a pound of powder, and boiling water enough to make it of a proper consistence for glazing the corn, rolls the seed in plaster, and plants, taking care to keep the grain moist. "It comes up rank," says Mr. P., "is larger at one week old than dry planted at two, and I am confident I have not lost a single hill the two past seasons. The smell is so disagreeable when prepared as above, that neither crows, birds, squirrels, field mice nor cut worms are disposed to meddle with it." Mr. P. asks if nitre and sulphur will answer the same purpose, and if yes, how much of each? Sulphur would no doubt prove a good antidote, and there would be no danger of using it to excess—yet we think tar and powder equally beneficial.

Lice upon Ruta Baga and Cabbage—In reply to the inquiry of Mr. C. Holbrook, of Woonsacket, we are sorry to state, that we know of no certain remedy against plant lice. Good manuring and good culture is the best remedy; though we think tobacco water or sulphur would expel them from the upper side of the leaves. If sulphur is used in a liquid, it may be first mixed with milk, and then blended with water.

A gentleman in Dorchester, Mass. asks if "there is any difference in the manner of growth, the size and quality of the leaf, between the Canton and multicaulis mulberry, and whether the former will stand our winters better than the latter?" The multicaulis has the larger leaf, and we think the Canton is the most hardy. See our article on the mulberry.

The Silk-Reel, a drawing of which we received from R. Mansfield, is the Piedmont reel recommended by the National Silk Convention. We will procure a cut, and insert and notice it in our next No.

"*Is there a cast iron Plough, of good construction, in use, with a steel point?*" is the question put to us by C. Ingalls, of Lockport. Norton's self-sharpening plough, sold by Wm. Mascraft, No. 23 Washington-street, Albany, is a cast iron plough of this kind. The point and share are separate, and are so formed as to be turned upside down, at pleasure, and made thus to sharpen themselves. This plough is said to have received premiums at New-York, Philadelphia, Baltimore and Washington, and its merits are highly spoken of by the patentee. Never having used it, we speak of it according to report, and not from personal knowledge.

On the subject of advice—A correspondent in Allegany last year described to us the quality of the soil in his neighborhood, and asked us how it should be managed, and now seems to take it unkind that we did not answer his question. A physician lays down general rules for the prevention and cure of diseases; but should he venture to prescribe in particular cases, without seeing his patient, or knowing the exact type of his disease, he would be apt to be branded as a quack. Now we have endeavored to make known the general principles of husbandry, to enable the farmer to improve his practice, leaving him to apply these principles to his particular case. Soils differ like the human constitution, and it would be as futile for us to prescribe, in many cases, as it would be for a physician to prescribe for an unseen and unknown patient. John Randolph once remarked, that a man at forty is either a physician or a fool; meaning thereby to imply, that in forty years experience a man of good sense will acquire a knowledge of his constitution, and of the best means of preserving his health. This will in some sort apply to the farmer. With a knowledge of general principles, the cultivator of a farm should know how best to apply them to his particular case.—This is his particular province and duty. There is no panacea in agriculture any more than there is in medicine. If land is poor, make it rich; if it is wet, make it dry; if it is badly managed, work it better. Ascertain the cause of infertility, or deterioration, and the remedy is palpable, remove or abate the cause. We have another apology for seeming neglect to answer all the special queries that are sent to us. They are very numerous, and the task of answering them, in a satisfactory manner, would be herculean. Under this view of the matter, we hope that none of our correspondents will construe our silence into intentional neglect—and that they will accord to us an honest and constant endeavor, to *do the most good to the greatest number* of our patrons.

Pitts' Thrasher—George Love's request will be submitted to Mr. Pitts as soon as he reaches Albany, which he is expected to do in a few days.

"*A Friend to Improvement*," can be gratified if he will permit us to use his proper name. Communications like his might be sent us from every county in the Union. We could not judge of their correctness; and without the sanction of a responsible name, both ourselves and our readers might be imposed upon with impunity. The precedent, it will be seen, would be a bad one.

Preparation of Clover Seed—We have received two communications from Joseph Warbasse, of Newtown, Sussex county, N. J., on the preparation of clover seed for sowing, by which the writer calculates he makes a saving of one half the seed required. This is a matter of no little consideration at the present price of seed. Mr. Warbasse's process seems to be predicated on the assumed fact, that ordinarily more than one-half of the seed sown does not germinate, either from the want of moisture to swell it, or of gypsum, the presence of which he considers essential to stimulate the germinating principle. Mr. Warbasse is probably right in stating, that one-half the clover seed sown does not come up; and he is strengthened in his supposition that much of it remains dormant in the soil by the fact he states, and which is of common notoriety, that plaster sown upon light lands, will bring in clover, where no seed is sown at the time. Mr. Warbasse's remedy for the evil is, to saturate and swell the seed thoroughly in soft water, to which a small quantity of salt is added, and after it has become well saturated, to coat it with gypsum, &c. the effect of which seems to be, to prevent the escape of moisture which the seed has imbibed, and thus insure its germination and growth. A further advantage may be, that the salts impart fertility to the soil which comes in immediate contact with the seeds, and causes a more vigorous growth. Such seems to be the philosophy upon which Mr. W.'s practice is founded. We give the process of preparing the seed in his own words:

"The seed is to be made thoroughly wet with a strong pickle from your pork cask, so as to wet the floor; then let it remain in a heap one day, it being thus made larger in each grain. In cold weather warm your pickle and give it an additional salting next day. Spread it about one or more inches thick on a dry floor, and in a few days a crust of salt will be formed on each grain, again enlarging it; when you wish to sow it, the weather being calm, moisten it with more salt pickle; spread it over a floor, and put on it about three quarts or more of plaster to a half bushel seed; mix it well; the plaster will adhere to the crust of salt on each grain, still further enlarging it; and thus you have in bulk nearly one bushel out of half a bushel of seed. Keep it moist in a cellar until you sow it, and take no more seed in your fingers but rather less than in the old way, making longer steps while sowing, and go over the eight-pace land three times. I have thus sowed twelve acres or more with one bushel of seed, and all in good condition.

For want of plaster, strong dry ashes may be used, not over moist; but as I have not fully tested the advantages of this method, I shall leave it as it is.

N. B. Those who do not fully understand the preparing of clover seed agreeably to the above directions, or are fearful of using the salt pickle, after having paid a high price for the seed, can prepare a water for steeping equally stimulating by boiling a few gallons of snow or rain water, and putting into it a fire-shovel full of plaster and a fire-shovel full of strong ashes or hot embers, with two hands full of salt. This water when cool, drain off and steep your seed in it two days, and before you sow it, wet it with milk, of any sort, this too will become an agent to encrust the seed with plaster, and so will any water, made slimy or oily; rye-meal would be better than milk to render it adhesive; starch and flaxseed put in while warm, might also be used to advantage. By following these directions you can sow twice as many acres and have better crops of clover without sowing any plaster on it the same summer."

Loss of the Cud.—D. L. Dodge, of Plainfield, N. J., wishes us to give a more full and connected statement of the nature, symptoms, and remedies for diseases in cattle, particularly for neat cattle and horses. This request shall be duly attended to. He at the same time apprehends, he shall lose a very valuable bull, in consequence of the loss of his cud. On this subject Lawrence directs:

"Let the animal fast some hours, then give a warm bran or pollard mash, with good hay, and warm water with salt. This treatment alone, may succeed with patience, even should the maw be obstructed by acorns or crabs. An aloe tincture, made with brandy and ginger, or capsicum, might be of use in this case. After conquering the obstruction, bitter infusions, made of chamomile, cardirus, horehound, oak-bark, &c. in beer, may be required as restoratives, although perhaps good dry nourishing food, will have an equal good effect."

Acknowledgments.—The Rock apple and a sample of a handsome seedling apple, from Mr. Verplanck, of Ballston. The Rock apple is the Carthouse, or Gilpin, of Coxe, excellent as a table apple late in the spring. Mr. V. says he has kept them till September. The tree is hardy, of handsome growth, and a great bearer. Grafts of a Siberian apple, a cross of the old Siberian, which keeps till midwinter, beautiful, large and fine from J. A. Thompson, of Catskill, an amateur pomologist. A peck of Timothy seed from Wm. Bristol, of Utica, perfectly pure, without the admixture of a single foreign seed.—The seed was raised by Asher Wilmot, of Paris, Oneida county, who raised some thirty bushels of like quality. Mr. Wilmot, in harvesting the crop, carefully takes off the heads of the grass, avoiding all foul seeds, from a strip, then cuts down the stubble, and proceeds to gather the heads from a second strip, and so on. Mr. W. deserves much credit for his care, and we hope to see his example imitated. A package of *Cedo Nulli* peas, a new and valuable variety, from G. C. Thorburn, of New-York.

CORRESPONDENCE.

Diseases of Sheep and Remedies.

Weybridge, Vt. March, 1839.

J. Buel—Sir—In the following communication, I have endeavored to give some directions relating to the management of sheep, and the most common discases, which are within my own experience, which, if published, I hope may be useful to wool-growers, who are unacquainted with their treatment and nature.

A healthy sheep will soon recover from those simple complaints, such as wounds, bruises and fractures, by a very little attention, if applied at the commencement; but by neglect a wound may soon degenerate into an ulcer. A broken bone sometimes may knit, the animal will suffer great pain, and probably have a crooked limb after.

Fresh wounds will suddenly heal, if closed by a stitch or common sticking plaster; small wounds at times need nothing, or a little tar is sufficient.

A fracture should be bound up neatly, with one or two splints, in flannel or other cloth, smeared with tar. Carc should be taken that the splints do not press the tender part.

Sheep are infested with several kinds of vermin, the common tick, maggot, &c; young and lean sheep are most exposed to these complaints.

Those flocks are not troubled with ticks, where the lambs are regularly immersed in a decoction of tobacco, say from four to five pounds to the hundred, about ten days after the sheep are shorn. Several pinches of Scotch snuff deposited in the wool, in and about the neck and sides, is a good remedy in cold weather.

Maggots originate from fly-blows upon the wounds; these are avoided by dressing with tar, and destroyed by an application of honey, when spirits of turpentine would prove ineffectual.

To cure *colds*, and running at the nose, a dose of tar, is sufficient, in the months of June and July; if applied at and above the nose, it will prevent the grub in the head and invigorate the health.

Nothing can be more safe or better to soften the hide, prevent or cure the scab, than a strong decoction of tobacco, applied to the parts infected. If the scab has become in a manner confirmed, it should be removed by a curry comb or otherwise; then after immersing them in a vat of liquor, lay them on an inclined table, which will conduct all the liquor that may be pressed from the wool into the vat again.

Sheep are frequently exposed to cold rains, or burning sun, immediately aftcr shearing, which will materially injure and sometimes destroy a number in a flock. Take train oil, or other cheap oil will answer, and with a brush lay a strip the whole length of the back and neck, which preserves them in a measure, from the pelting storms, a scald back, and destroys ticks and other vermin, adds to the weight, and encourages the growth of wool. By the addition of a little sulphur, it will prevent the scab and keep off flies, which annoy them during the summer.

The *stretches* is a common and very fatal complaint. Wethers of three years old and over, are more apt to be its victims. When attacked they stand bracing on all fours, like the legs of a stool, and refuse to eat. The cause originates from air being pent up just forward of and below the hip. My treatment for this, is to give the animal a gill of hogs fat, and draw it about suddenly for sometime.

The *foot-rot* is an infectious disorder, which locates between the hoof, and unless immediate attention is rendered, it operates under the horns of the hoof; it is more easily cured in the winter or when the infection freezes. If thoroughly seated, it cannot be entirely eradicated from the flock in warm weather, unless they are permitted to run in a fresh pasture, where there is no exposure after the treatment, which is this: first, the foot must be pared, if infected, and all the ulcerous matter removed; then apply with a swab, zig or water strongly saturated with finely pulverized blue vitriol; when thoroughly done the rot will be removed, and the foot will be healed in four or five days. It is very important, that the diseased animals should be separated from the flock. Fine woolled sheep, and those that have long hoofs are more subject to the rot, and more troublesome to cure. It spreads by innoculation only, and rages worse in low, wet grounds. It is important that they should be examined every week until cured, which will require three or four thorough examinations, where the ulceration is confirmed.

By using a trough, the description of which you have in the cut below, the foot can be examined with ease, and it is a great saving in time and labor.

[Fig. No. 7.]

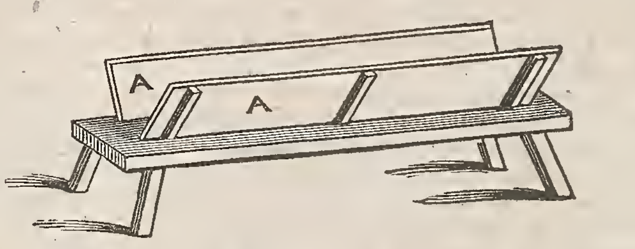


Fig. No. 7 represents a trough, which will conveniently hold two sheep, with their feet uppermost—the frame simply consists of a plank about six feet in length, in which four legs are fastened eighteen inches long; six arms are extended from the upper side of the frame, which supports the side boards A, A, six feet long and thirteen inches wide, and forms a trough about one foot in width at the top, and four inches at the bottom; this trough should stand one end near the door of another dry yard, where the sheep must remain an hour or so, after the application of the vitriol, which should be applied between the toes of every foot. By the assistance of this apparatus, three men can go over from three to four hundred sheep in one day. With respect, yours,

S. W. JEWETT.

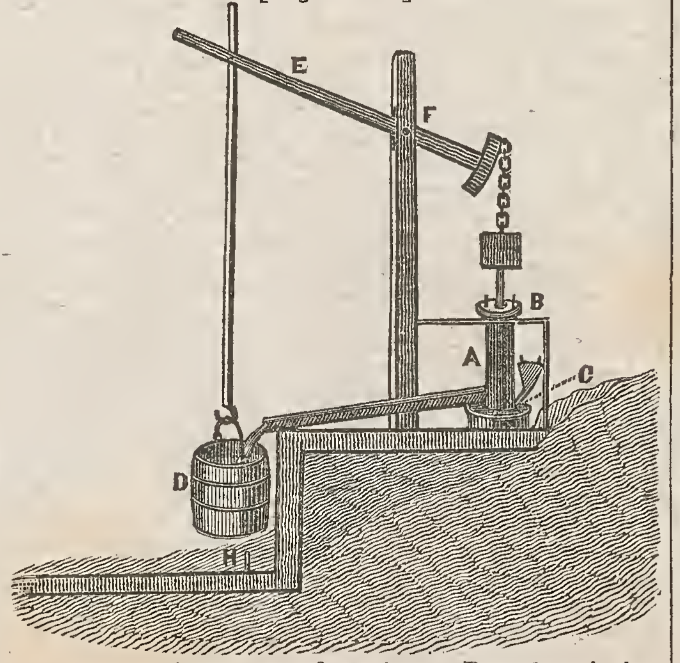
Method of raising Water.

Kingsbury, February 1st, 1839.

Hon. J. Buel—Sir—In the April number of the Cultivator, Mr. Curtis, of Vermont, inquires as to the cheapest method of raising water to the height of 100 feet or upwards. Nothing adds more to the comforts of a farm house, or to the cleanliness and health of it inmates, than the luxurious flowing of a pure stream of water at the door. I have often, while riding past, observed the want af this necessary element around the houses and yards of our farmers, while the perennial fountain was flowing in the richest profusion, within a short distance, but unfortunately on a lower level, and as often have I wished to see some cheap and efficient engine at work, making the babbling idle brook turn itself to some good account, and pour the necessary share, at the door, a libation to *neatness, temperance, industry and economy.*

In Gregory's Dictionary of Arts and Sciences, an engine is described, under the head of Hydraulics, which, by its simplicity, promises better than any thing else I have seen. For the purpose of calling attention to that article, and for the benefit of those who may wish to see it, and have not that work at hand, I have made the following rough drawing, which you may publish or not, as you shall deem expedient. This engine was invented by a Mr. Sargent, who received a silver medal, from the Society for the Encouragement of the Arts. It had been in operation, with *complete success*, for some years, when the article was written for the Dictionary. A gentleman's hall, it seems, was situated on an ascent of sixty-one feet perpendicular height, and the engine supplied the hall with water from a small stream which ran at the foot of the hill, 140 yards distance.

[Fig. No. 8.]



A, is a forcing pump, of cast-iron. Bore three inches in diameter. B. weight attached to the piston rod; this weight is so heavy that when drawn up, and left to descend, it forces the water in the pump up the ascent, through the pipe C, which is one inch in diameter. E, is a lever, the fulcrum of which is at F. A perpendicular fall must be had in the stream, of about four feet, below the level on which the pump stands. To the edge of this descent the water is brought in the trough G, after supplying the pump, and flows into the bucket D. When this bucket has acquired a sufficient weight of water to raise the piston, with its weight B, it immediately descends until it strikes the pin H, which lifts a valve or clapper in the bottom of the bucket and lets the water out. The bucket, relieved of its load, is brought by thc descending power of the weight B, to the position shown in the cut, the lever turning on the pin F. It will be seen that this engine will operate with a very small supply of water; for whenever the bucket is filled and emptied, there must be a stroke of the piston. The end of the lever to which the bucket is fastened should be elevated as much above the level of its fulcrum as the botton of the bucket is above the pin H, so that when the bucket begins to descend, it will acquire additional velocity by the virtual lengthening of the lever, and will strike the pin with force sufficient to lift the valve. The pump has a solid piston; also a valve in its bottom opening inward, and another opening outward, in the pipe C. Yours,

L. B. ARMSTRONG.

Butter making—Ruta Baga—Value of apples for Hogs.

Milton, Ulster Co. 2d mo. 1839.

Respected Friend, J. Buel—Through the columns of the Cultivator is a very convenient and extensive way of asking questions, and giving such information as we may have observed, that we think would be beneficial to mankind.

I would ask of the readers of the Cultivator, something relating to butter making. Although it has been treated pretty largely upon through the Cultivator, there are some things come under my observation, that are unaccountable to me, and to others I have conversed with on the subject. The latter part of sixth month last, in the warmest or hottest part of the month, we were unable to obtain more than about one pound of butter from five cows in a day; the milk would curdle before it was sour; the cream would rise but little and would be ropy, and in pouring out of a pitcher, would string like molasses or soft soap; we used every remedy we then thought of, to remedy the evil; every attention was paid to the cows, in giving them salt and good running water; they run in a fine growth of clover, and gave a bountiful quantity of milk. From three of the same cows, we made one and a half pounds of butter per day, before the hot weather commenced. I have never observed but once before in twenty years, milk appearing in the way it did at the time mentioned. I inquired of some of my neighbors, if theirs was similarly affected; they said not, but complained they made but little butter. My wife, since then, has suggested the idea of milking three times a day, when the weather is very warm. Eevery attention was paid to the milk things.

Since taking the Cultivator, some in this neighborhood have been induced to undertake the raising of the ruta baga, and generally are well satisfied, except one or two, who have tried them, and because they will not answer in the room of all other fodder for stock, consider them not worth their attention. I have used them for milk cows, and find whcn they are fed on good sound roots, and not those that have been frozen or a little defected, that the butter does not have that unpleasant taste, or but very little, so that those that have not been in the practice of eating butter made whilst feeding cows on turnips, to which we would refer, thinking we had become accustomed to eating, and could not perceive it, say they did not perceive any unpleasant taste. We perceived it when we first began to feed them, as we perceive an unpleasant flavor when cows are turned in the clover, in spring of the year; I attributed that to feeding them some of the tops that got a little spoiled, before feeding in the fall.

As there has been much published in the Cultivator as to the worth of apples in fatting hogs, my experiments may hardly be worth filling the columns of the Cultivator with; if not, thee is at liberty to lay them aside. In the fall of 1836, I put up eight shoats in the pen to fat, weighing them at the time, which was 105 pounds the average weight, and calculated what they were then worth, or what I could sell them for alive at that time. I then kept an account of the apples, potatoes and bran; but used principally apples, and boiled them and mixed the bran with them as I took them out of the kettle. I began before the apples were fit to make cider of; I valued the apples at twelve and a half cents per bushel, and the small potatoes at eighteen cents, and the bran what it was worth at the mill, and added the expense of the wood for cooking; when killed, they were worth $1.50 a piece more than what they ate, valuing them at ten cents per pound, what such pork was then selling for, having the rough fat for my trouble, and not reckoned in the weight when killed. By this it would appear that apples are worth one shilling per bushel for fatting hogs, when pork is worth ten cents per pound.

J. SHERMAN.

Experiments with Leached Ashes.

East-Hartford, Conn. Feb. 1839.

Friend Buel—As your motto is for the "improvement of the soil and the mind," permit me through the medium of your widely circulated and valuable journal, to give publicity to a discovery in the preparation of leached ashes, or soap boiler's waste, so as to make them equally valuable, and perhaps more so, to the farmers of our vast interior, as to the cultivators on Long-Island, where thcy are bought up at an expense of 35 to 50 cents a bushel, and considered a profitable investment at that. The vast quantities bought annually in this country, (where they are considered of little value, and of none on clayey land,) and shipped to Long-Island, induced me to think that the saline matter in the soil and atmosphere, was more the cause of their wonderful effect upon vegetation, than any *inherent* quality in it. To give theory the test of experience, I mixed ashes with common salt, but the salt was too coarse and too long in dissolving, to combine chemically;—the next was to sow the salt and the ashes afterwards: this did better;

my next to wet the dry unleached ashes with a strong brine, and after standing a sufficient time to spread readily with a shovel, applied them as a top dressing to turnips and potatoes. In this last experiment the success met my highest expectations; the potato crop was quadrupled, and the difference in the turnip yield still greater; but the soil as in the application of all high stimulants, should have a moderate dressing of *some* kind of manure, and it will be found in excellent order for grass or grain afterwards.

It may be observed of crops manured and dressed in this manner, that the leaves appear of a bright pea green, instead of the darker green, denoting too much top—whilst the tuber of the potato, and the bulb of the turnip, showed the whole strength of the plant to have centered there. To carry the analogy still further, I have given the land a liberal dressing of plaster after the ashes so prepared, but not the least benefit to the crop could be perceived, any more than if it had been used within a mile of the ocean—of course it was labor lost.

The object of this communication, Mr. Editor, is not for the purpose of telling what I have done, or what I can do, to enrich and beautify this footstool of the Almighty, for I am but *one* amongst millions, *and the least among ten thousand*; but to draw the attention of my brother farmers of our vast and limitless interior to the preparation and use of an article hitherto considered a drug and a nuisance.

It is very desirable that some enterprising farmers of each county in the western part of yours, and of other states, where leached ashes are in abundance and useless, to try the experiment of wetting them when dry, with strong brine, no matter how old or stale, (if the price of salt is too high,) and communicate the result in the Cultivator. The lands found best adapted to this kind of manure on Long Island, are the poorer description of sandy and gravelly soil, and this agrees perfectly with my short experience here; so far, then, nature is true to her own laws, and no doubt every farmer in our wonderfully active climate and productive soil, will find the same striking analogy verified by experience. The season is approaching for the proper time of trial—let it be upon corn, potatoes, grass, upon spongy wet land, or newly stocked down, turnips and wheat in autumn, and should it come up to the writer's expectations, I shall think my past life not wholly spent in vain. Yours respectfully, DANIEL EASTON.

REMARKS.

The experiments detailed in the above communication are worthy the attention of the farmer and the chemist. Two facts have long been known, the causes of which we have never seen satisfactorily explained. One of these facts is, that leached ashes are found to operate as beneficially upon Long-Island lands, as unleached ashes, or more so—leaving it to be inferred, that it was not the potash which the ashes contained that induced fertility. The other fact is, that leached ashes operate more surely and beneficially within the influence of the marine atmosphere, than they do in the interior—thus inducing the belief, to adopt the language of our correspondent, "that the saline matter in the soil and atmosphere, was more the cause of their wonderful effect upon vegetation, than any *inherent* quality," which they possess. The experiments of Mr. Easton go to warrant this conclusion. But *how* they exert this agency, is a question worth investigating; and we commend the matter to the notice of some of our chemical correspondents.—*Cond.*

Treatment of Wounds on Horses.

Georgetown, D. C. February, 1839.

Wash the wound morning and night with warm soap suds, and anoint immediately after washing, with whale oil.

Having used this remedy for a number of years, *at all seasons of the year*, I can confidently recommend it to others. It purifies and heals the wound as soon as is desirable for soundness; protects it from *cold and flies* and the hair is *always* replaced, of the natural colour of the animal. J. A. D.

Inquiry in regard to Lime—Ruta Baga, &c.

New-York, February, 1839.

JUDGE BUEL—Sir—Being a subscriber and constant reader of the Cultivator, I have one request to make of you, or some of your able correspondents, for which I shall feel much obliged for an answer in your March number or as soon as convenient, viz —In what way can lime be applied in the spring, to a wheat field, or is it proper to apply it at all, after the wheat has made its appearance above ground?

I have a farm in the northern part of Cayuga county, principally sandy, gravelly soil. Ruta baga have done well, on the dry parts of it, having been cultivated for four years past, and found to answer an excellent purpose for all kinds of stock. In looking over your correspondents' experiment as applying different exhilerating properties to the soil, I have frequently regretted, they were not more particular in stating the nature of the soil, whether clay, loam, sand or gravel. Several years since I had occasion to make free use of leached ashes, on a clay soil, which I found to answer an excellent purpose; subsequently I have applied it on sandy soil, without an apparent great advantage.

I was lately in conversation with an honest, intelligent man from the cabbage raising district in New-Jersey, to whom I was complaining that I could seldom get more than one in twenty cabbages to head. He at once gave me the reason; he says there is not much soil that will answer to raise cabbage over one year; that it requires new land, ploughed in the spring, reploughed and made as tender as possible until the fourth of July, when the plants should be set out and a handful of unleached ashes thrown in and about each plant.

AGRICOLA.

REMARKS—It is not common to sow lime upon a growing crop, though a small dressing, early in the spring, say three or four bushels an acre, would not, we think, do injury, and might do good.

Accident to Horses.

Rappahannock, co. Va. Feb. 26th, 1839.

J. BUEL, Esq.—Sir—Having been a subscriber to your valuable paper, (the Cultivator,) for some months; I find that it is designed for general utility and the public good; therefore I desire to make known, thro' that medium, an accident to which horses are liable, perhaps little known to the public. In the year 1818, I had a sick horse, and after using the usual remedies without relief, as the last alternative, I fixed a gag for the purpose of running a mop down the throat, for I believed the horse was partially choaked. In this preparation, I accidently discovered part of a corn cob tight across the roof of the mouth, which had prevented the passage of any food to the stomach, save the juice occasioned by mastication from repeated attempts to eat. The cob was removed by a smooth stick as large as a man's thumb, sufficiently long to extend into the roof of the mouth. I was then cautious not to let the animal eat much at a time, until it recovered. I have since relieved several horses from the same accident, and I have no doubt thousands of our most valuable animals have been lost from the same cause, without ever knowing of what they died. I will here remark, that it is sometimes very difficult to find the piece of cob, and remove it after found, for it will become very tight and nearly concealed by the swelling and inflammation. I trust this will find a place in your paper, which may be of benefit to some of your numerous readers. Yours, &c.

JNO. D. BROWNING.

Beneficial effects of Draining.

Springfield, Feb. 17th, 1839.

Mr. J. BUEL—Sir—In perusing the pages of the Cultivator, I have noticed frequent allusion to draining of wet meadows, and reclaiming of waste lands, a branch of agriculture which, as far as my observation extends, receives quite too little attention, from our agricultural community.

I am induced to send you my experience, in this branch of practical farming, in the hope that the attention of some may be called to this subject, who have hitherto overlooked the advantages to be derived from it. I am the more led to do this, under the apprehension which, I believe well founded, that many, who are in possession of waste lands, have either not had their attention sufficiently directed to this subject, or having made a partial attempt to reclaim such lands, and having failed to realize their expectations, through want either of knowledge or perseverance, as in the case I am now about to mention, have given it up in despair, as impracticable. The first piece of meadow to which I would direct your attention, contains from four to five acres; it is eighty rods in length, and from eight to ten rods in width; it was abundantly supplied with cold springs, running in on either side, and when an attempt was made, some thirty or forty years ago, to bring it under cultivation, large drains were dug on either side to carry off the springs, and when that was done *all* was done, (as was then supposed,) that was necessary for the purpose of draining it sufficiently. The plough was then applied, and by great labor and perseverance, the whole meadow thoroughly subdued and mellowed, and sown with oats and grass seed; but the experiment failed entirely. There was no crop, either of grain or grass, the superabundant water having killed the whole, and nothing grew but weeds and various kinds of water grass, of no value at all, except it be to be mown and used as litter either for the hog-pen or barn-yard.

Thus the meadow was given up entirely as irreclaimable, and remained so for more than thirty years, entirely unproductive. My attention having been called to this subject by reading and observation, I determined on making a further experiment. Accordingly, in August, 1835, I caused a ditch to be dug through the centre of the meadow, throughout its whole length, at an expense of twenty-five cents per rod, four feet wide and two feet deep, being fully convinced that superabundant water was the cause of its sterility. I then prepared one-half of the meadow for the plough, by scraping the banks of the ditches on either side into the low places where water would be likely to settle, &c. In November following, I ploughed the land well, and in the following spring, I planted it with potatoes, without ploughing again, after having harrowed in a very scanty portion of fine manure upon a portion of land. My crop of potatoes was four hundred bushels by measure.

The next season, I planted the same land again with potatoes, together with the other half of the meadow, and my crop was seven hundred bushels. Owing to the distance of the meadow from my barn, and the difficulty of access, I have been able to supply it with but a scanty portion of manure, and some of it none at all.

The following season, I laid down the first half of the meadow to oats and grass, and pressed the surface well with a roller, (an article which every farmer should have,) and thus prepared the land for the successful operation of that important auxiliary in gathering heavy crops of hay, the horse rake. I confidently expect that this meadow will prove to be as valuable and productive as any land I have.

Another piece of meadow, I have, which was supplied with springs on one side only, and I well remember some forty years ago, that my father, at considerable expense, caused a large ditch to be dug to carry off those springs, but without effect. The meadow was still wet, full of bogs, and cranberries, &c. &c. and in some places a cart wheel would sink into the hub. It was thought sufficient if the ditch was dug deep enough to come to the hardpan.

By reflecting upon the subject, I was convinced that the water, (there not being descent enough to allow the water to pass off quickly,) soaked down into the meadow, on the surface of the hardpan, and thus kept the soil saturated with water, and prevented its productiveness. I caused the ditch to be sunk six or eight inches into the hardpan, and thus confined the water in the ditch, and by this means succeeded in laying the meadow dry.

The obvious inference from the above facts is, that thorough draining is the first thing to be attended to, in cultivating wet meadows; without it, *labor* and *manure* are wholly lost.

I offer you these hints, sir, for your consideration, and if you think the publication of them would subserve the interests of the agricultural community, you are at liberty to make what use of them you please.

CHAUNCEY CHAPIN.

The Grain Worm—Feeding Turnips—Legislative Engcouragement to Agriculture.

Otisco, February 19th, 1838.

JESSE BUEL, Esq.—Respected Sir—I last evening received the last number of your excellent paper, and on looking it over this morning, observed a request that the wheat-worm of our part of the state should be described to you, by me, or some one else, and I have sat down to describe its appearance now, lest I should forget to do it hereafter.

The worm which is called the *wheat-worm* in western New-York, belongs to the genus *Phalærna* of Latrielle, (*Geometridæ* of Stephens,) and according to Wilson, embraces above eighty species. By people in general, this class of worms is usually called surveyor, carpenter, or measuring worm, from the manner in which their movements are effected. The number of legs varies in the several kinds from ten to twelve; but in the wheat-worm, there are six pair, three at each extremity. Like most other worms of this genus, it has the power of spinning a web, as may be seen from the facility with which they, when disturbed, attach themselves to straws, sides of the threshing floors, fanning mills, &c. The worm varies in length, from three-eighths to five-eighths of an inch in length; and some may possibly a little exceed the latter estimate. Between three-eighths and half an inch, may, however, be considered their average length. The colour is very uniform: a *yellowish brown*, or what among farmers would perhaps be termed a *butternut colour*. Under the microscope, it appears studded with these yellowish brown spots, divided by lighter coloured spaces: but to the naked eye the colour seems continued. That it is the larvæ of a fly or moth, cannot be doubted; though of what particular kind, does not as yet seem satisfactorily ascertained. This worm has been known for years among wheat, in this part of the state. Three or four years since a farmer assured me that in cleaning up a quantity of wheat threshed immediately after harvest, he gathered in the boxes of the fanning mill, nearly a bushel of these same worms. His wheat had of course suffered, and he was very apprehensive about his next crop: but that was entirely free, nor had he been injured by them since. It is not so much the new appearance of this worm, as its increase, which has created the present alarm respecting it. From experiments which I made the last year, by enclosing the worms with a quantity of carefully selected grains of wheat, in a muslin covered vial, it is clear that the worm feeds not only on the kernel in its soft or milky state, (though that is the time when the most serious injury to the grain is accomplished) but also after it has become hardened by ripening. It is probable, that, like other caterpillars, it continues to eat till it undergoes transformation, or dies. In none of my experiments, did I find a kernel perforated after it had become hardened; but they were gnawed off by the worm, and usually from the germinating end of the kernel.

I have seen in wheat in this part of the state, but it was many years since, a worm or rather maggot, which perforated the kernel in the manner of the pea grub, and which apparently lived on the interior of the ripened grain. In this case it seemed to me, the egg must have been deposited in the kernel while in a soft or milky state. However that may be, the worm was clearly a different one from that I have above attempted to describe; and which at this time appears to threaten the grain growers of this district. Unless I have forgotten, there is in the November number of the Cultivator, an account of the perforating worm, which struck me at the time, must be identical with the one I have alluded to; but it has not since 1824 shown itself to any extent in our wheat.

It is certainly very desirable that it should be determined whether the worm of the western part of this state, is identical with that which has proved so destructive in the valley of the Hudson, and over New-England. I have been inclined to suppose, from some notices I have seen in the Maine papers, that the worm I have described was the one which was so injurious there. At any event, the size, colour, and habit, will, I think, be sufficient to enable us to come to a satisfactory solution of this point. As you have unquestionably had ample opportunities for observation, I should be pleased to learn from you your opinion as to the difference or identity of the wheat worm of the east and the west.*

I have seen in some of the newspapers, an account of several horses being killed at Malone, on the farm of a Mr. Sabin, by his allowing them to feed freely on turnips partially heated and rotted in the pits, from want of ventilation; and the inference is drawn, that though excellent for cattle and sheep, they are unfit or poisonous for horses. This I think is an error. For several years past I have been in the habit of having them fed to horses, as daily food in the winter and spring; and some of my neighbors have also used them extensively for this purpose, and without the slightest injurious effect in any case that I have been able to learn. Spoiled turnips, like spoiled potatoes or rotted grain, may acquire deleterious properties, and should not be fed to animals; but I think no farmer need be apprehensive of injury in feeding sound roots to any animal whatever.

I have read with much interest, the brief account of the meeting of the State Agricultural Society that has appeared in the papers, and shall look with interest for the report in a more detailed form. What we wish is, to excite a proper sense of the importance of agriculture, among those in high places, and then we may expect that something will be done for its advancement, in the establishment and endowment of agricultural schools, and county societies. Agriculture is clearly the grand interest of this state, and in all the legislation concerning it, should be so viewed. I cannot think the present session will pass, without some proper and useful action on the points most interesting to the cultivator of the soil. I have been led to hope much from the *domestic* production of silk; and hope to see such encouragement offered as shall cause its advance, if possible, in this way. As a people, we are given to humbugs, and the short horn and mulberry speculations will, a few years hence, be looked upon, not the least magnificent of the class. Both are very valuable, both are deserving of extensive introduction, but the order of nature must be reversed before the present state of things, so far as the Durham and multicaulis are concerned, can long continue. Yours, &c. WILLIS GAYLORD.

Farming in East Maryland.

Smyrna, (Md.) February 19th, 1839

Hon. J. Buel—While writing on business, I will say a word of our country between the Delaware and Chesapeake Bays. The system of agriculture heretofore has been ruinous to the land. It was get all you can, and make little or no return to it; but for the last eight or ten years, our farmers appear to be convinced of their former errors, and are giving their attention to the improvement of their lands; and the effect is, our country is fast changing for the better—lands are going up in price, although now, farms with good improvements, can be bought at from $10 to $20 per acre. I have travelled through the western states, and Iowa, and Wisconsin territories, and as far south as Missouri, and I am satisfied from two tours through that country, and from all the information I could get, that better investments can be made in land on the peninsula, between the two bays, than can be made in any of the western states. Our immediate vicinity to the Baltimore, Philadelphia and New-York markets, the freights being from five to six cents per bushel, and nineteen out of twenty farms being within five or six miles of tide water, must always give us an advantage over those remote sections. And again, the high price of labor is a great drawback in that country; and if we cannot make as many bushels per acre as they can there, we can make as many dollars clear per acre; for I am convinced that every dollar we lay out on our land, nine times out of ten we get paid back in the first crop, and our land is increased in value. A few years past, I purchased some poor worn out land near this place, that would not bring ten bushels of corn to the acre; and I have improved it, principally, from the resources and products of the land. I had a lot of 2¾ acres and 8 rods enclosed, which was in clover in 1836. I cut the clover twice in 1836; in October of that year, I covered it with about 130 one horse loads of cow and horse yard manure, and flushed it under in the fall of 1836; and in the spring of 1837 flushed again, and planted it in corn; the rows seven feet apart—dropped, as near as we could, two feet apart; left two stocks in a hill; and a row of potatoes between each row of corn. In the fall of 1837, we got 149½ bushels good sound corn, and 315 bushels potatoes. The corn at 85 cents, the market price, is $127.07; 315 bushels potatoes, at 35 cents, the market price, is $110.25; gross amount, $237.32½, being $84.76 per acre. My friend and townsman, George W. Cummins, Esq. last year, cut from 39 acres 2 roods and 15 perches, 992¾ bushels red wheat, average weight 60 lbs., making a fraction over 25 bushels to the acre.

I make these statements to show what our land will do with attention. None of this land is in a high state of cultivation. Some part of Mr. Cummins' wheat, it was thought, would cut 40 bushels to the acre. I think I can say we have not one waste acre to the 1,000, clear of the influence of the tide; that our country is remarkably healthy, and that we have all the good things the bays and rivers furnish: and yet, with all these advantages, for the last 20 years, you will discover our population has been nearly stationary, owing to the mania for emigration to the south and west.—Many persons wishing to emigrate, a few years past, would sell off their farms for much less than their buildings cost, and give away perhaps 300 or 400 acres of land, nearly worth $20 the acre with proper management; but I am pleased to say the thirst and mania for emigration has almost ceased. Many have gone and spent the labor of years, and returned; and now they can appreciate our country. I saw in my western tours, persons from New-York state in the west, land speculators, who, if they would come and view our country, could not but be pleased with it. Persons of information who have travelled much through the United States, say this is the garden spot of the United States. BENJ. BENSON.

We suspect Mr. Benson is right in saying, that Maryland and Virginia offer better bargains to the enterprising farmer, than are generally found at the west. The lands in the former *can* be rendered productive—and they enjoy advantages of markets, &c. which must be a great drawback to the interior west.—*Cond.*

Criticism on the Mulberry.

Mulberry Farm, N. J., March 5th, 1839.

J. Buel, Esq.—Dear Sir—In the last number of the Cultivator, I find an answer from a gentleman aggrieved by your valuable remarks and criticisms in the January number on mulberry venders and growers. I am sanguine in the belief, that the mulberry culture and silk growing will be both mystified and retarded by the disposition many venders of the tree have to impose new names on plants that differ so slightly by climate, soil and cultivation from their natural history characters; thereby confusing the plain and honest grower with new names—creating a fear that he is cultivating the wrong variety of the mulberry. That this prevalent speculative spirit, (unsanctioned by any principles of botanical nomenclature whatever) is productive of evil consequences only, there is not the slightest doubt; and the result is, many are prevented from embarking largely in this important branch of national agriculture. I cannot see, for the life of me, the advantage gained, either by individuals or the community at large, by this multiplicity of names imposed on one or two varieties of the mulberry. In a late number of the Farmer and Gardener, the editor, when speaking of Multicaulis, Alpine and Moretti, says, "the Alpine mulberry, so called, is not known in Europe by that name, having received its own cognomen from Mr. Whitmarsh, etc." In a measure, this remark is applicable to some other kinds, at least so distinguished. The mulberry in question is cultivated in Italy, within the region of the Alps; hence its name, Alpine. Botanical men, I fancy, know it by the name of Morus Alba, var. Italica, in allusion to the country where it was first grown. It is stated that the Dandolo, Moretti, Multi, &c. came from France and Italy; but no such plants are recognized there, except by gardeners, who are continually coining new names. By calling this plant an Alpine, that a Manilla, it does not prove that that country is the habitat of either, because neither are a species, but can be produced at any place, "*et ceteris paribus*," by climate, soil and cultivation. Then Mr. Whitmarsh has, with equal justice, the same privilege to call his plant Alpine, that others have to call their's Expansa, Rigida, Dandolo, or any other absurd name, (each identical, or differing in no essential character,) provided it is not to the detriment of truth, and prejudice of individual advancement. It would be a little more definite, setting aside the principles of naming plants, to call them all Multicaulis: thus, Alpine Multi, Moretti Multi, Dandolo Multi, Mannilla Multi, &c. This may be done with as much propriety as the Morus Alba, var. Macrophylla, is called Morus Multicaulis.—The following supposed species are mentioned by some of the gardeners, who are continually making mere varieties into species, and will elucidate the absurdity of new coinage: for instance, the *Morus rubra*, commonly called red mulberry, may be called Morus Virginica, Pennsylvanica, &c. in contra-distinction to Morus rubra, because its habitat is North America, and it flourishes in all the states. *Morus Tartarica*, habitat, on the grounds overflown by the Volga and Tanais: pronounced a mere variety of *Morus Alba* by Sprengel, the author of the latest complete work of descriptive botany. *Morus Italica*, habitat Italy, pronounced a mere variety of *Morus Alba* by Sprengel.—*Morus Sinensis*, habitat China; the Alpine, Dandolo, and Moretti, I fancy, are improved from the native *Morus Italica*. The Canton is taken from *Morus Sinensis*, while the Manilla and Multicaulis, I apprehend, are types either of the *Morus Latifolia*, *Morus Australis*, *Morus Mauritania*, (Jacq,) *Morus Anipolis*, (of Poir,) *Morus Insularis*, (Foster?) whose habitats are Persia, the Mascarenhas and Madagascar Islands.

In recommending the several varieties of the mulberry to the attention of silk growing enthusiasts, the largeness of the leaf is particularly descanted upon, as if that feature is the great and paramount object. As far as my experience and observation extend, it is a mistake to suppose that the largeness of the leaf is the great disideratum. For one kind of plant may produce leaves twice as large as some others, yet contain less fibrous substance, of which silk is assimilated. As this is the case, then, in aiming to procure plants producing such large leaves of vigorous growth and forced cultivation, we lose sight of the fact that those leaves contain less fibrous matter, but more succulent substance, than leaves of smaller dimensions of slower growth, and more compact in texture. Again, all the forced varieties deteriorate when left as standards, and the ordinary culture in such cases bestowed on them, while the amount of foliage is not so great by one-half. If a leaf of the Multicaulis, measuring 6 by 10 inches, contains no more nutriment proper for the worm than a leaf of the Brousa measuring 4 by 6 inches, wherein consists the advantage of the Multicaulis over the Brousa or other varieties? If such is the case, then two-thirds of the leaf is superfluous, and must be thrown off as excrement by the worm; for all of the component parts of the leaf, in a measure, not fibrous, is almost of absolute waste. It is said that worms prefer the leaves of the Multicaulis to all other varieties.—This is purely speculative. If two different varieties of leaf of the mulberry are given to two or more worms, they will invariably eat of the leaf nearest to them, without manifesting any sign whatever that they are displeased with their food, or prefer one kind to another. They are no epicures. Well fed worms move about but little; it is the half starved ones that roam; and they are so uneasy with the pains of partial hunger, as to eat but little and taste often. We have a vast deal yet to learn on this subject, and many will, no doubt, meet with disappointments when they have counted largely the gain, without knowing the cause of failure. A year or two will suffice to bring us to our senses on this subject; and then, I opine, we will grow silk advantageously, realizing only a fair profit from capital invested, instead of the erroneous returns given by theoretical and visionary men.

But I find I have nearly spun my sheet out and must close. I have hastily strung a few words together to fill this sheet, as a passing tribute to another year's subscription to your valuable paper. I enclose the amount. Very respectfully, &c.

J. N. KEELER.

Drawbacks upon the Farmers Profits—Ruta Baga.

J. Buel—Sir—Many readers of the Cultivator, who are not practical men, have been led to form extravagant expectations in regard to the pleasures and profits of farming, from the report of some of your correspondents. They read of the extraordinary nett revenue of some highly cultivated acre or field, but don't hear of the many losses and failures which might be told; and some, from this partial view of the subject, have embarked in the business, with anticipations only to be disappointed.

I belong to the "new school" of agriculture, if the term may be used, and am passionately fond of my profession, yet entirely practical, and moderate in my hopes of profit. I could tell of the almost total failure of the corn crop, for three successive years, after expensive preparation, and on land which has yielded ninety-nine measured bushels of corn per acre. Of wheat, too, we all know the loss suffered in attempting to cultivate it for three or four years. For successive years, the average nett profits are good, if the business is well conducted; but many will be disappointed if they would become rich in a minute, and that without care and labor.

Those who write for farmers, should remember that they are plain, common sense men generally, and are apt to be offended with any utopean schemes.

To renovate an old meadow, which cannot be ploughed, I pasture with sheep for one or two seasons. The sheep should be in number sufficient to bite it very close; they should then be turned out, and the grass be permitted to grow a few weeks. This should be repeated several times in the season. I have seen a most surprizing effect from this plan.

I must state a fact in regard to ruta baga. I fatted a beef principally with this root, which was fed to him until the day before he was butchered. It imparted a very unpleasant taste to the meat. The milk and butter of some cows that were fed upon the roots, were also slightly affected; and what is worse, sir, my friends ascribe all the mischief to Judge Buel. Now, notwithstanding this, I believe the ruta baga will become an important crop. N. REED.

Amenia, Dutchess co.

☞ Judge Buel has always directed, that cattle fattened upon ruta baga should be taken from that food ten days before they are slaughtered; and that milch cows fed upon them should have daily access to salt. In Great Britain, many thousand beef cattle are annually fattened upon ruta baga.

Management of Horses—Reading.

Schenectady, 20th February, 1839.

Hon. Judge Buel—If we could, we would most cheerfully aid you in the herculian task you have undertaken, to combat the popular errors and prejudices in farming; in the improvement and employment of useful labor-saving machines, the best mode of making and using manures and treatment of the different breeds of animals.

We see that you often meet with mortifying trials; but my friend you have learnt the use and exercise of patience with your subscibers and readers as with children, for we are children of a larger growth. It is much more easy to lead than drive. We approve, much, your calm mode of answering useless questions. But, you must allow free inquiry from us who are ignorant; for we must ask questions, or remain in ignorance like children, who ought always to be answered in all their inquiries, however trifling. The answer should be to inform and interest.

My son labors with farmers to persuade them to subscribe for the Cultivator, by showing the variety of matter therein exhibited, and the extensive scope and collection of all the experiments and improvements in the wide extent of all the United States, and beyond. But it is rare that any are willing to pay the dollar, although they would cheerfully accept the Cultivator as a gift. We ask them, wherein is a man better than a horse, if he does not know more than a horse? That knowledge is power, and the horse is better than the man who has no more knowledge, for the horse is stronger; and power without knowledge to direct it, is dangerous.

---

* In our report to the agricultural convention inserted in our last, we expressed our belief, that the wheat-worm of the east and of the west were *not* identical. Mr. Gaylord has confirmed that opinion—*Cond.*

We will give you an anecdote of a man living in the neighboring town of Niskayuna, but half a dozen miles from the great city of Albany, the capital of the Empire State, where light is supposed to radiate in meridian splendor. This man, with great self confidence and pride, told how he could cure a horse of the bots. His horse was ill of the bots, and he took a tea-kettle full of boiling water to pour down his throat. His father interrupted him, so that he succeeded in pouring down the horse's throat only half the tea-kettle of boiling water. In truth, the horse was immediately dead—he opened him, and found *just half* the bots were scalded to death, when he exulted, by saying, that if his father had not interrupted him, he should have succeeded in destroying all the bots, and proved the usefulness of his discovery. We remarked to him, that it was an unprofitable mode to kill his horse in order to destroy the bots. Oh, he said, he could easily have saved the horse, by pouring down his throat an equal quantity of oil, to heal the injury of the scald, if he had not been interrupted. He told this in great flourish, exulting in his valuable discovery in medicine.

Now, sir, how will you correct such folly, except it be by cultivating and improving the intellect of such stupid men? The best English writers on farriery, say, that no horse is ever injured by bots; and we believe it. Horses are subjects of the inflammation of the bowels, cholic, apoplexy, &c. as men are; and giving them cold water, or exposing to cold winds, to take colds when wet with sweat, &c. produce those diseases as they do in men.

Water as warm as the horse's blood is, may be given to him at any time, with impunity. It is the cold that injures him. The horse should never be watered at the well. Brook water and rain water are the safest; if the brook is distant from its source—a cold spring. So the smith will always cut off some of the frog and bars under the horse's foot, when he shoes him, because he does not know that the maker of the horse, placed the bars there to support the hoof, and preserve it from closing up. This repeated, ruins the hoof, and injures the foot. The smith who shoes my horse, is told, that when he cuts the frog or bars, he will not be allowed to shoe him again. Farmers must read, or they cannot improve.

My object in giving the anecdote is, to show you the great ignorance existing in the neighborhood of the renowned city of Albany, and the necessity of compelling farmers and mechanics to read, that they may improve.

They will acquire a fondness for books, if they would begin and practice reading useful books. They should be compelled to pay a tax, to be added to such public bounty as the legislature may offer on that condition; and then they will read to share the tax.

"*Gather up the crumbs, that nothing be lost*" is a most valuable injunction.

Every farmer and mechanic, and their sons, spend the evening hours of almost every day idly. If those crumbs of time spent idly were employed in reading proper books, all would be instructed, and many would become learned, and even eminent. Whereas, by idleness and neglect of those crumbs of time, in which they can earn nothing, if rightly employed, we should not meet any such grossly ignorant men as the one who killed his horse, by pouring boiling water down his throat to save him from bots.

The value of time is not understood. It is the great capital for obtaining the greatest and best riches both of this life and the future. When the poor man says *he has no time*, he speaks not the truth. Our great Creator, in the distribution of time, is perfectly just and impartial, for he gives to every one the same and equal measure of time. Instead of justifying such complaints as waste of time, he will answer, I gave to every one alike, and some have abused the precious gift, by folding their hands in idleness. Farmers must read, and then they will improve. Most respectfully,

DAVID TOMLINSON.

Agricultural Association for Mutual Improvement.

Spottsylvania county, Va. 25th Feb. 1839.

Sir—I enclose a preamble and regulations for the establishment of an Agricultural Association, formed upon a plan suggested in the fourth volume of the Cultivator No. 12, page 194. By the unanimous vote of the members of this association at their first meeting, I was requested to forward them to you for publication.

Very respectfully, I am your ob't serv't
WALTER HOLLADAY.

J. Buel, Esq. *Conductor of the Cultivator, Albany.*

NORTH ANNA AGRICULTURAL ASSOCIATION.

That our agricultural systems are radically defective, the increasing sterility of our lands sufficiently proves. That it is our interest to improve them, if in our power to do so, none will deny. Good crops cannot be obtained, for any great length of time, upon farms made every year more barren by injudicious cultivation.

It is owing to the worn-out condition of our lands, that hundreds of our citizens annually abandon the homes of their fathers, to seek a residence in the rich countries of the West. We have reason to believe, from the success attending new modes of cultivation, now in operation in various parts of the United States, that these impoverished lands may be restored to their original fertility: perhaps even *made better* than they ever were.

However *this* may be, it is believed to be a fact established by experience, that almost every farmer may improve his land, slowly indeed, but *surely*, with the limited means which may be derived from his own farm. And certainly it requires no argument to prove, that an approximation towards fertility, though slow and gradual, if it be continued for a sufficient length of time, must ultimately reach it.

Nothing, then, is needed, but the adoption of better systems of husbandry, persevering industry, and a skilful application of the means within our reach, with the blessing, *at all times*, of Him who giveth "rain in due season," to make our lands productive of all that can be necessary to the comfortable subsistence of man. *He* that abuses the *ordinary* gifts of Providence, is held to be highly reprehensible, under every system of moral duty. What, then, shall be said of those who abuse the greatest of all sublunary blessings bestowed by God upon man, a soil capable, under proper management, of supporting human beings in comfort, *for all time to come.* By one of the most distinguished agriculturists of our country, such persons have been denominated "matricides," *murderers* of the bountiful mother of us all.

We have persevered in the agricultural systems of our fathers, because practically we knew of none better. If we heard of others recommended as better, we shrunk from the adoption of them, under a conviction that *we* at least, possessed neither the means nor the skill necessary to carry them into successful operation. We were in possession of lands covered with trees, which had been growing for ages in all the luxuriance of nature. We knew how to cut down, and to remove these; to plant, and to gather; to sow, and to reap; according to the practice of our fathers. The rich products of these lands, fresh from the hand of nature, prevented us, for a time, from feeling in its full force the effect of our system. *Three-fourths* of such of these lands as were fertile, have been divested of their natural growth, and subjected to the action of the plough: crop after crop, for years in succession, taken from them without manure, or repose under artificial grasses; until they are reduced, as we all can witness, to a deplorable state of sterility. Shall we *yet* persevere in this ruinous system?

It is, indeed, no easy matter for us to divest ourselves of habits transmitted from father to son, for a period of more than two hundred years. Nothing, perhaps, short of necessity can be expected to effect a change in them. Does not that necessity exist at the present time? It has been approaching us with rapid strides for years past, and, as we think, may now be seen, in a greater or less degree, in the impoverished condition of the fields of every farm around us.

Convinced of the truth of these positions, on which it cannot be necessary to dilate, we whose names are hereunto subscribed, agree to form ourselves into an association, to be called the North Anna Association, for the attainment of knowledge on agricultural subjects.

This association shall be conducted upon the principle of mutual instruction, by the interchange of opinions relative to the improvement of our husbandry, and the management of our farms. With a view to these objects the following subjects are proposed, as particularly claiming our attention: The best modes of collecting the manure and litter of a farm; the best way of preserving them, when collected, if not wanted for immediate use; and the best modes of applying them to the crops that may be cultivated, having regard to the permanent improvement of the land.

The use of plaster of Paris; on what soils and crops its operation is most beneficial; the quantity necessary to the acre; and the best time for applying it.

The rotation of crops most proper in our soil and climate. The species of Indian corn most productive with us; the best security against the chinck-bug and the cut-worm; and the best modes of cultivating and securing this valuable grain, having regard to the product and the economy of labor.

The species of wheat most profitable to the farmer; the proper quantity of seed to the acre; the most approved modes of preparing the land for the reception of the seed; and the best way of guarding against the ravages of the fly.

The cultivation of rye and oats; which of these crops is most valuable to the farmer; and the best modes of raising them.

Whether root-crops are adapted to our soil and climate, and if so, the most approved methods of cultivating them.

Whether the making of tobacco be consistent with any good agricultural system, and if so, what that system may be.

The best time for sowing clover seed, and the proper quantity to the acre.

The best method of making and securing clover hay.

Live stock generally; the breeds most profitable to the farmer, in our part of the country, and the best way of keeping them in good plight throughout the winter, having a due regard to economy.

The ploughs and other agricultural implements most approved for durability, and their adaptation to the purposes for which they are intended.

PARTICULAR REGULATIONS.

For the purpose of aiding us in our inquiries relative to the above subjects, or any others which may be deemed important, we agree to take, in our associated capacity, the Farmers' Register conducted by E. Ruffin, the Cultivator, conducted by J. Buel, and such other agricultural publications as the association may hereafter choose to take, which shall be read at our meetings, or such parts of them as may be required to be read.

Meetings of this association may be held as often as once a month, at the discretion of the members; never at intervals of more than six months.

When necessary for the transaction of business, this association shall be organized by the appointment of a chairman, to preside for the time at its deliberations, and a secretary, whose appointment shall be permanent, to record its proceedings. Six members at least shall be required to form a quorum.

Each member shall be liable to a fine of twenty-five cents for failing to attend a meeting, unless he shall be excused at the next meeting by a majority of the members then present.

It shall be the duty of the secretary to report to each meeting such members as may not have attended the last meeting; to receive the amount due for fines from the members respectively; and to keep the funds, books, papers, and other property of the association.

As this association is voluntary, any member may withdraw from it at pleasure, by communicating to the secretary his intention to withdraw, and causing his name to be erased from the list of members.

Effect of Steeps.

Mr. J. Buel—Dear Sir—Mr. Hathaway's letter, published in the June number of the Cultivator, giving his opinion that steeping Italian spring wheat in strong brine for a length of time was injurious to its vegetating principle, has induced me to make some experiments in the case for my own satisfaction. The results have not been what I anticipated, and I think it my duty to communicate them. They certainly go to prove that gentleman to have been correct.

The wheat on which I experimented was the Italian; the berry fair and plump. The pickle was impregnated with as much salt as the water would dissolve. Parcels containing twenty-five kernels each were steeped for different periods of time, and placed in moist earth, marked in such a manner as that they might be easily distinguished, and suffered to remain undisturbed until the greater part of the stems made their appearance above ground.

RESULT OF FIRST EXPERIMENT

No. 1,	25 kernels,	steeped	5 minutes,	2	did not vegetate.
2,	do	do	30 do	2	do
3,	do	do	1 hour	4	do
4,	do	do	18 do	12	do

[2 kernels missing.

The result of the parcel steeped 18 hours being unexpected, I made another trial, which was as follows:

No. 1, 25 kernels well washed in brine—every kernel vegetated.

No. 2,	25 do.	steeped 4 hours,	2	kernels did not vegetate.
3,	do.	8 do	6	do
4,	do.	12 do	11	do
5,	do.	18 do	13	do

It seems from the above, that the injury sustained is proportioned to the length of time the grain has been steeped, and that if it has been steeped 18 or even 12 hours, almost one half loses the vegetative principle.

I am fully satisfied that pickling and liming of the seed is an infallible preventive of smut in the wheat crop, but I do not think that steeping for 10, 12 or 18 hours is necessary. This opinion is founded on my own experience and observation, as well as the long practice and experience of others. My method has been, to make the brine as strong as I could, permitting the wheat to be no longer in it than is necessary for washing it, and skimming off whatever floats on the surface; when taken out it is mixed with fresh slaked lime and sown soon after. With this preparation, even when the seed is impregnated with smut (as was the case last year with part of the Italian wheat that I obtained) the crop has been perfectly clean. Liquoring, as it is called, has been practised in the wheat growing districts of Scotland for these forty years past; how much longer I do not know; but even so long ago as at that period, good farmers would almost as soon have thought of throwing their seed into the sea as they would have thought of sowing it without that preparation. Brine made from salt or sea water, or otherwise, and stale chamber ley were used, the latter most generally. When chamber ley was applied, the usual method was to sprinkle it on the heap of grain until it was well wetted; add fresh slaked lime, and sow immediately. In the application of brine, some steeped for a longer or shorter time, and others sprinkled. Without liquoring, in nine cases out of ten the crop was smutty; with it, *never*. I will conclude with a quotation corroborative of what I have just stated. "There is some danger from the first, for if the seed steeped in urine is not immediately sown, it will infallibly lose its vegetative power. The second, viz. sprinkling the urine on the seed, seems to be the safest if performed by an attentive hand; the last brineing may do equally well, if such a quantity of salt be incorporated with the water as to render it of sufficient strength. But it may be remarked, that this last mode is often accompanied with smut, owing no doubt, to a deficiency of strength in the pickle, whereas a single head with smut is rarely discovered where urine has been used."—*Treatise on B. Husbandry.*

JAS. SMEALEE.

Princetown, March 4th, 1839.

The old Colony yet.

Post-Office, Pembroke, Mass. March 2, 1839.

Hon. J. Buel—Dear Sir—I think the farmers of the old Colony have been much benefitted by the diffusion of agricultural information through the columns of the Cultivator. For one, I am free to acknowledge that I am not too old to learn, and that I have derived much information from reading your valuable paper; and you will confer a favor on me, as well as others in this section of the country, by giving your opinion of the adaptation of our soil for the cultivation of roots, (ruta baga, mangold wurzel, sugar beets, carrots, &c.) and their relative value as a crop to Indian corn, taking into consideration the exhaustion of the soil, &c.* We are just beginning to think that roots can be cultivated to advantage on our soil; that they can be profitably fed out, not only to our working oxen and store cattle, but to milch cows; and that an immense amount of the most valuable winter food for stock can be raised on an acre of land.

A considerable portion of our lands in the Old Colony are silicious loams, or light sandy soils; and much of it has been exhausted by bad tillage; by a close adherence to the old division of farms into *mowing*, *tillage* and *pasturage;* by constantly cropping the tillage land with corn and rye, with a scanty allowance of manure; never cultivating green or ameliorating crops, nor suffering it to rest and recruit (under a system of alternation of crops) with clover and other grasses; and the mowing land having remained in the same state since the *departure* of the Pilgrim fathers. We have some good soils, but much of our best lands are yet unreclaimed; our bog meadows and swampy lands are capable of being converted into fertile English meadows, and will richly repay the proprietors for all the labor and expense bestowed upon them in a very few years; but the most of them lack energy; our young men have been told that our soil is exhausted; that the soil of the West is *inexhaustible;* therefore they all make tracks for the far west but him to whom the homestead falls, and our population and our agricultural improvements remain in "*statu quo.*"

But the tide of emigration will have its ebb; it will yet be found out that the Far West, with all her rich alluvions and verdant prairies—with her agues and fevers, is a less formidable competitor for agricultural success, when compared with the soil of New-England, with her healthful and invigorating climate, than has generally been supposed. I am, sir, &c.

HORACE COLLAMORE.

Renovating worn out Land.

West-Suffield, March 1st, 1839.

Hon. Jesse Buel—Sir—I purchased, some years ago, a lot of land made poor, very poor, by the exhausting system of our fathers; the soil sandy. It produced no more than about 5 or 6 bushels of rye on an acre. I fenced it into convenient fields, and commenced the following rotation: first, hauled on all the manure I could spare, at the rate of about 26 ox cart loads on the acre, spread it evenly on the surface, and turned it under with a plough, harrowed lengthwise of the furrow, and planted with corn, potatoes, beans, &c. the manure unfermented; and planted no more than I could manure.—Second year, a broadcast crop, *i. e.* oats, rye, &c. with clover and timothy seeds. Third, fourth, and fifth years, pasture or meadow. The land previous to my occupation having been ploughed continually, this was necessary to obtain a sward, and to have the land consolidate. My corn produced 30 and 33 bushels, rye 10 and 12, and oats about 20 bushels per acre. Sixth year, in rye, sowed on the first furrow, or a naked fallow was substituted. Three times each method was pursued in the same field, in the same season; one, that which was sowed on the first furrow yielded much the best; the other times it was not so productive.

I would recommend that neither practice be pursued, but that the land be broken up, and oats sowed on the first furrow, and that the stubble be turned under for rye, with clover and grass seeds. This year will finish my rotation, when I shall have manured my lands once over. My neighbors admit that my land will now produce double that it would when I commenced my rotation, and without extra labor.

I propose next year, if my life should be spared, to commence my second rotation with increased means, from the fact of saving more manure from increased crops, and more knowledge obtained principally from your valuable journal: first year giving my manure to hoed crops; second year to small grains, with clover seeds; third year to pasture or meadow; fourth year, rye, or wheat, on the first furrow (of a clover lay) with clover and grass seeds for permanent meadow or pasture; that when I begin my third rotation I may have a good rich sward to feed my corn and potato crops. Thus I have doubled the produce of my lands within eight years without extra means or labor, simply by a judicious application of such means as every farmer possesses. Yours, JOHN NOBLE.

Singular change in the quality of Soils.

Suffolk County, Feb. 26th, 1839.

Sir,—You stated in the last Cultivator, that wheat cannot be depended on without the application of animal matter, or lime. I will state you a few facts as regards wheat. With us wheat was raised from the first settling of the county until 1780, or 90; it then failed. About that time we began to get fish, which were used for rye, which did well. It was no uncommon thing to have 40 bushels to the acre. For wheat they did not answer, neither did any other manure.—Farmers, as a general thing, gave up trying to raise it. At the present time, wheat is a far more certain crop than rye, and has been for years past. Rye has been failing for years past, and latterly many pieces have been cut merely for the straw. Here is a complete revolution in the two grains. You will say the soil has been modified by the action of manure. Take a piece of land that has not been manured from the first clearing to the present time, and you will have the same result, that is, you will probably have a fair crop of wheat, and little or none of rye. Corn has not fluctuated; it has been a steady crop, and governed by the seasons. Oats—the same. Flax has run nearly the same round as wheat and barley. The above has particular reference to the south branch of the island, Suffolk county. We have been troubled these two or three years past with a worm that starts a few inches from the head, goes the length of the straw, and comes out near the ground. It does not injure the crop materially, on account of its coming out late; it cuts the straw off about the time, or a little before, the wheat is fit to cut. I do not recollect seeing an account of it, but it may be an old acquaintance of yours. Raising wheat is an expensive business with us. The first cost of manure is from 20 to 30 dollars per acre. In favorable seasons, wheat does well; we sometimes get 40 bushels to the acre, but that is a great yield. I will conclude by wishing you may infuse a little of common sense into our legislature. Yours, &c. S.

Remarks—The facts above stated, with regard to the remarkable change in the properties of soil, are new to us, and are worthy of philosophical investigation. We will not hazard a conjecture as to the cause, with the few facts before us, but we invite an investigation by more competent hands. Let the western farmer note, that manuring in Suffolk costs 20 to 30 dollars an acre, that with even this expense, farming there is profitable, and that the soil there, before it was worn out, was probably deemed as good as it now is at the west. It is easier to preserve than it is to restore fertility.—*Cond.*

American Society for the Diffusion of Useful Knowledge.

To the Editor of the Cultivator:

Sir—Your paper for January, contains a communication, dated "Concord, N. H., Nov. 24, 1838," making charges against "The *American Society for the Diffusion of Useful Knowledge,*" and those by whom it has been managed, which are of such a nature, that we feel it to be due, not merely to ourselves, nor yet solely to the society with which we are connected, but also, and most especially, to the great interests of our national education, that they should not be allowed to go before the public unanswered.

We speak in sober sincerity, when we say, that we consider, that this matter most especially concerns the great interests of our nation's education. We pretend not, that such charges against a society, on which we have bestowed much labor and thought, and which we believe, is becoming an instrument, by which may be effected great good to our country; much less, that statements aspersing our private characters, fall upon our ears, without producing sensations of sorrow and pain: still, our hearts are not so bound up in that society, as to be unwilling that its objects should be effected by other means; and we must be allowed to say, that we have no fear, that our characters rest upon such frail foundations, as to be overthrown or even shaken, in the only sphere in which they are of value to us—the circle of those who know us, and with whom the affairs of life bring us in contact—by assertions imputing to us such gross fraud, as those contained in the communication referred to. But when we look at the effect these statements must produce in the public mind, if they meet with general belief, we cannot but perceive, that almost a death blow is given to every hope of ever enlisting the mighty influence of united effort, in the work of supplying the urgent wants of our people, for sound education and healthful knowledge.

If it be possible, in these days of light, when a vigilant press is watching every enterprise which concerns the public interest, and conveying on the wings of the wind, every rumor to the most distant hamlet, if it be *barely possible*, in these days, that "a few individuals who care for nothing but the profits of the concern," can prosecute a speculation in books, under the pretence of diffusing useful knowledge, and publish to the world, "without their knowledge or consent," the names of many of the most respectable and benevolent of our citizens in every part of the land, as approving the plan and its execution, and not one intimation be given to the public, by one of those, with whose names so gross a liberty has been taken, that they know nothing of the society or its plans, when will the people know whom to trust? Well may our people, although conscious of the pressing need for united effort on this important subject, and willing, each to contribute his share to the great work, pause before they do anything; and resolve to confine themselves to the feeble endeavors of individual effort and unconnected influence, if so unscrupulous an attempt "to do a good profitable business" out of the intellectual and moral wants of our nation, can be suffered to go on, under the sanction of such names, without one warning being given, by those, whose fair reputation has been made the cover of so unprincipled a speculation.

Under these considerations, the subject assumes importance: by these considerations, and these alone, are we induced to notice the attack made upon us.

Your correspondent's statements will be considered in the order in which he makes them. The first is in the following words:

"It was stated that the members of that society, or most of them, were elected without their knowledge or consent."

"I found that many of the individuals named as members, were made members without their knowledge or consent.—And some of my friends were among the number."

As no list of the *members* of the society, has ever been published, your correspondent evidently does not refer to members properly so called. He undoubtedly refers to the names printed, in the first part of each volume of the published library, as those of presidents, vice-presidents, &c. Every gentleman so named, was regularly elected to the office assigned to him in that list; and notice of his election was sent to him.

Some signified acceptance of their appointments, in written or verbal communications; others, by attending meetings in the capacities, which the list referred to, represents them as filling.

By all such, we consider their appointments to have been formally accepted.

To all the other gentlemen, were written or printed notices of their appointment sent, and, they were deemed to have accepted the same, from never having intimated any disinclination to accept it: but not until after the lapse of ample time, for returning an answer declining the appointment, without receiving any such answer, was the name of any one gentleman published.

We give below, all the names in the list, together with a statement of the manner in which their appointments were respectively accepted.

President—Hon. Stephen Van Rensselaer, formally accepted.

Vice-Presidents.—Governor Marcy, Albany; Hon. Albert Gallatin, and Hon. Reuben H. Walworth, New-York; Francis Wayland, D. D. Rhode Island; Hon. Theodore Frelinghuysen, and Hon. Samuel Southard, New-Jersey; Hon. Wm. Robertson, and Hon. Wm. C. Rives, Virginia; Gov Duncan, Illinois; Henry R. Schoolcraft, Esq. Michigan; Governor Everett, and Hon. Daniel Webster, Massachusetts; James Milnor, D. D. New-York; Hon. Ruel Williams, Maine; Hon. Roger M. Sherman, Connecticut; Thomas Sewell, M. D. District of Columbia; Hon. Henry Clay, Kentucky; have formally accepted.

Rt. Rev. Benjamin T. Onderdonk, New-York; Hon. Franklin Pierce, New-Hampshire; Hon. Robert C. Greer, Pennsylvania; Hon. Roger B. Taney, Maryland; Gen. James Hamilton, South-Carolina; Hon. Henry Hitchcock, Alabama; Hon. Alexander Porter, Louisiana; Hon. Felix Grundy, Tennessee; Rev. Charles P. McIlvaine, Ohio; Governor Dunlap, Maine; Hon. Horace Everett, Vermont; Hon. Horace Binney, Pennsylvania; Hon. James Bayard, Delaware; Hon. William Gaston, North Carolina; Hon. John M. Berrien, Georgia; Hon. Robert J. Walker, Mississippi; Hon. Thomas J. Lacy, Arkansas; John C. Young, D. D., Kentucky; Hon. William Hendricks, Indiana; Hon. Lewis F. Linn, Missouri; are the other gentlemen named in the list as vice-presidents, and have each had, a written or printed notice of his appointment, sent to him, and, from not one of them, has there ever been received any communication declining it.

Board of Directors.—Alonzo Potter, D. D., John Knox, D. D., Jacob Janeway, D. D., Rev. John A. Vaughan, Rev. Gorham D. Abbot, and Hon. Benjamin F. Butler, New-York; Hon. Samuel J. Armstrong, Massachusetts; Hon. John Sergeant, Pennsylvania; Peter G. Stuyvesant, Esq., Hugh Maxwell, Esq., Charles Butler, Esq., James Brown, Esq., Eleazer Lord, Esq., Thomas Cock, M. D., John T. Gilchrist, Esq. and Samuel W. Seton, Esq., New-York; Israel Collins, Esq. Pennsylvania; Thomas McAuley, D. D., Thomas De Witt, Rev. George Potts, Rev. John Proudfit, Hon. Samuel Jones, Hon. Heman Lincoln, David Graham, Esq. Hiram Ketcham, Esq., Timothy R. Green, Esq., Cornelius Baker, Esq., John Griscom, L. L. D., Anthony P. Halsey, Esq. and Robert Kelly, Esq. New-York; Thomas J. Wharton, Esq. Pennsylvania; have formally accepted.

Hon. Samuel Hubbard, Massachusetts; Frederick A. Tracy, Esq. and Francis L Hawks, D. D. New-York; Benjamin Silliman, L. L. D. Connecticut; Hon. Myndert Van Schaick, New-York; Bradford Sumner, Esq. Massachusetts; George S. Robbins, Esq. New-York; Isaac S. Lloyd, Esq. Pennsylvania, have had written or printed notices of their appointments sent to them, and have never directly or indirectly declined to accept it.

Executive Committee.—James Brown, Esq. Chairman, and John Torry, M. D. New-York; Alonzo Potter, D. D. Schenectady; Wilbur Fisk, D. D. Connecticut; Rev. Jacob Abbot, and Rev. Bela B. Edwards, Boston; Rev. Leonard Bacon, New-Haven; Charles Butler, Esq. and Thomas Cock, M. D. Lewis C. Beck, M. D. N. Y. University; Wm. Cooper, Esq. John T. Gilchrist, Esq., Timothy R. Green, Esq., Marinus Willett, M. D, Wm. Betts, Esq. and Henry E. Davis, Esq. New-York, have formally accepted.

To the Rev. Calvin A. Stowe, of Ohio, printed notice of his appointment was sent, and no communication declining it, has been received.

Gorham D. Abbot, *Secretary*, and Anthony P. Halsey, *Treasurer*, have formally accepted, and are now fulfilling the duties of their respective offices.

These facts speak for themselves, and completely refute the charge of gentlemen being "elected without their knowledge or consent.' We would add the remark, that the executive committee, are, as their name imports, the acting portion of the society; those, on whom the proper management of its concerns directly falls: that the board of directors, by the constitution, under which they were elected, and which has been printed and extensively published, are designed, to meet but once a year, unless specially convened, and to exercise a general superintendence over the executive committee.

The office of vice-president, as is well known, is an honorary appointment, involving no labor other than, perhaps, presiding at some public meeting.

We believe, that the receipt of a notice of appointment, without returning any intimation of unwillingness to fill the office, is considered an acceptance of it.

It will be seen, that the highly respected gentleman, who was named as our president, had, formally accepted the office. That of the vice-presidents, thirty-seven in number, seventeen have formally accepted. Of the Board of Directors, thirty-nine in number, thirty-one have formally accepted.—Of the Executive Committee, seventeen in number, sixteen have formally accepted.

We will only add, that our libraries have been extensively published, every book in them containing the above list; our prospectuses, notices, advertisements and circulars, most widely spread over the whole country, with the above list of officers; and we have never, from any one gentleman named in that list, received any communication, directly or indirectly declining his appointment.

The next charge is in the following words:

"The whole matter was managed by a few individuals, who cared for nothing but the profits of the concern." "The amount of it is, that the society was planned by Mr. Abbott, the secretary, and more as a speculation, than any thing else." This statement comprizes two charges—first, that Mr.

---

* Satisfactory answers to these question will be found in our report upon root culture, made to the State Agricultural Society, in the March number, and in our essay upon root culture in the present number.—*Cond.*

Abbot planned the society, and that a few individuals managed it. Secondly, that it was gotten up and managed as a speculation.

The first charge literally construed, amounts to nothing.—To say of the society, that it was chiefly planned by one man, and was conducted by a few; is only to say, what is notoriously true of every society that ever existed, especially in its earlier stages, and most particularly in our country, where all who have ever been connected with benevolent institutions, have experienced the great difficulty of getting our busy citizens, to attend to matters unconnected with their own affairs. But the charge conveys more than this general fact; it intimates that it was a plan, secretly devised by Mr. Abbot; and that its management was studiously confined to a few. To this construction of the statement, we can only give a flat contradiction. That to Mr. Abbot's persevering activity, in bringing before the minds of some of our most enlightened and influential citizens, the vast importance of enlisting the mighty power of the press, in the service of our national education; and to the light, thrown upon the subject, by the mass of valuable information, which he had collected from similar institutions in England, the existence of the American Society for the Diffusion of Useful Knowledge, is chiefly owing, all know, who know any thing of its origin and formation: and that on a comparatively few has fallen the labor of managing its affairs, is also true.

But it is utterly untrue, that the organization and plan of the society, were the work of Mr. Abbot, either alone, or in concert with a few individuals only: or that its management, has been intentionally confined to a few. The formation of the society, was the result of the mutual consultation of many gentlemen of the highest public and private character. Its plan was discussed and finally adopted in public meetings, held in this city, which were called by notices in the newspapers, declaring the object for which they were convened; and throughout its whole existence, an extensive correspondence has been carried on, with distinguished citizens all over the country; and the executive committee, have eagerly availed themselves of information and advice from every quarter, and earnestly endeavored to procure the active aid of their fellow-citizens. No one can regret, more than they do, that greater numbers do not engage in this most important cause; and none are more willing, that every step which has been taken, by the comparatively few, who have heartily engaged in it, should be spread before the eyes of our whole people.

As to the other part of the statement—that the society is a cloak for speculation, we feel degraded in even contradicting so gross a charge; but, as entrusted with the management of a society, professing to promote public interests, and seeking for support from the public, under the sanction of most honorable names, we feel it to be due to the public, and particularly to those, who are thus indirectly charged with silently lending their influence to a disgraceful trade, to state briefly what the society has actually done, which will at once refute the charge of speculation; and also, what is conveyed in the following portions of the communication under consideration.

"I find that the library of 50 volumes, is made up of the old volumes of the 'Family Library,' and the 'Girls' and Boys' Library,' printed from the old plates, and the only variation was in the binding. (These series were published by Messrs. Harper, of New-York.")

"Besides, the committee of the society consented to make a statement, which is little less than downright deception."

"Under the head of 'EXECUTION OF THE PLAN,' it is stated, 'all the arrangements for carrying the design into execution, are in a state of forwardness, so far as they can be, before the necessary funds are secured.' It is estimated that $15,000 are required to manufacture the stereotype plates for 50 volumes," &c.

"Now, the very volumes offered, are printed from plates that have been used several years, and on examination of some of the volumes, you will find that they have *two title pages*, one 1835 or 1836, and another 1838—proving that they were printed two or three years ago!!!"

"If publishers wish to get off their old stock, let them say so; but, in the name of heaven, let not the friends of education come forward with any plans of deception."

These charges, we say, will be fully refuted by a brief statement of what has been actually done.

After its organization, the society proceeded to ascertain by correspondence with authors, printers, and others, how best to carry its plans into execution, and what funds would be necessary for that purpose; and learned that $15,000 would be requisite; and so stated in their published prospectus, as quoted above—and most happy would the society have been, could they have raised "the necessary funds;" those funds, as the prospectus stated, were the only thing wanting: but, unfortunately, before they could be raised, that season of commercial distress, from which our country is but just now beginning to recover, came on, and it were superfluous to add, that it was impossible to raise any thing like the sum proposed.

The statement annexed, shows what funds have been raised by the society up to this date, and how they have been disposed of. It is enough here to state, that the stereotype plates for the fifty volumes have never been manufactured, *because the* $15,000 *have never been raised.*

After having made ineffectual efforts to raise that sum, and in the midst of the gloomy period alluded to, the society received information, from the public authorities of this state, of an appropriation made by the Legislature, for the purchase of Common School Libraries; an appropriation, which rendered it morally certain, that $110,000 would be expended in this state, during each of the years 1839, 1840, and 1841; and that most probably, at least that amount, would be annually expended for that purpose, for some time afterwards. It was obvious, that libraries of some kind or other would be purchased; and it was also obvious, that, unless some competent and disinterested persons should undertake the selection and publication of such libraries, it would be more than probable, that they would be composed, in part, at least of books, whose introduction into our schools and villages, might prove any thing but a blessing to the state, and might be purchased at prices, which greater harmony of action would have materially reduced.

In this emergency, the society again looked over the field, to ascertain how they might best further the enlightened and benevolent views of the legislature. It found itself without resources to induce authors to compose original works; without the capital, necessary to undertake the publication of a library on its own strength; without the power to do any thing further than to select a library from existing publications; and utterly unable to do that, unless through the agency of some publishing house of established character. The alternative presented to the society, was not whether to publish such a library as they originally intended, or such as they did publish; but whether to publish such as they did, or leave our common schools to be supplied, for a time at least, with libraries at hap-hazard, by those to whom pecuniary profit must be the chief consideration, and who would be under no responsibility whatever, for the character of the books they furnished.

In the words of the prospectus, which is prefixed to every volume of the published library, and which we are sorry, has not chanced to meet the eye of your correspondent—"The increasing interest in the subject of school libraries, *and the repeated calls* upon the committee for their library, have induced them to issue the present *selection* from *existing publications*, to suit the *immediate* wants of common schools, while they *go on as fast as possible to complete the plan announced in the published prospectus.*"

As to the character of the books composing that library, we will speak presently.

The committee, among other publishing houses, had their attention called to that of the Messrs. Harper & Brothers, of this city. In the establishment of those gentlemen, they found many works already stereotyped, from which, although not having every quality, which, we hope, will be found in those prepared by the society; were yet of excellent character, and would form a portion of a good library, which would meet the emergency, which demanded immediate attention, and compelled the society to depart somewhat from its original plan. After much deliberation, the committee accordingly made an arrangement with the Messrs. Harper, of which, the first series of the "American School Library," is the result.

It was agreed with the Messrs. Harpers, that the committee should publish a library of 50 volumes, which should be mainly selected from works published by those gentlemen, and make such alterations as should be practicable; that the whole should be neatly bound in an uniform style, with title pages, denoting them to have been published under the direction of the society; and the 50 volumes should be arranged in neat boxes, which, both served as enclosures for their transportation, and as book-cases when they had arrived at their place of destination. Each box was to be handsomely painted, and furnished with a printed catalogue of its contents.

The price at which similar publications had been sold to the reader, was fifty cents per volume: the library published by the society, bound more neatly than the ordinary style, and arranged in cases, in the manner above described, costs the reader twenty dollars for the fifty volumes, or forty cents per volume. So that one effect of the arrangement was, to reduce the price of the works, published under the direction of the society, one-fifth, or twenty per cent. In other words, 100 volumes with a book-case, are now bought, for what formerly bought but 80, and deducting the cost of the book-case, for what formerly bought 74 volumes. It must also be remembered, that the former price referred to, was that of works published with a view to most extensive circulation, and was put at a rate intended to attract purchasers by its lowness. The only provision made for the society, was an appropriation of a portion of the proceeds, for the purpose of enabling it to employ agents, in effecting the introduction of the library into the various school districts.

Such was the arrangement with the Messrs. Harpers: how far it will prove profitable to those gentlemen, we know not; but whether they should, or should not make money by it, affects not the question at issue: The question which was presented to the executive committee, at the time alluded to above, when they felt bound, though unable at once to do what they had hoped, yet to do what they could to meet the immediate emergency; which was, whether they should make some such arrangement as the one just mentioned, or leave our school and village libraries, for some time to come, to be supplied by those, whose main motive must be the hope of profit—and depend for their selection, in many instances, on those, whom neither education nor experience had fitted for the task

The society adopted the former alternative, under a feeling to do so. It may prove profitable to the publisher, but whatever pecuniary advantage he may reap from it, dwindles into insignificance, compared with the substantial benefit reaped by the country, from having hundreds of well selected libraries distributed throughout the land; and valuable works put at a price, that enables the most needy to purchase them.

The executive committee have believed, that their publications were unexampled in cheapness; they may be under an error, but if so, it arises from want of information.

The charge of speculation, is, in other words, that the projectors of this enterprise, were chiefly moved by the hope of profit. Now, as to the publishers, we must at once admit, that in all human probability, the chief motive impelling them to form arrangements with the society, was the hope of gain. If there be one, who expects that printers will print for nothing; that binders will convert the fluttering leaves into the compact volume, without compensation; that capitalists will lend the use of funds, without expectation of any return; he may perhaps be disappointed, when he finds that it required the hope of profit, to induce the firm who manufactured the School Library, to put into operation the complicated machinery of their establishment. We frankly say, that if there be persons with such views, we despair of ever gaining their approval. We expect to pay a profit to every paper-maker, every printer, every binder, every carpenter, who furnishes paper, ink, thread, or book-case for our publications; and hence arises the necessity of raising funds, before we can proceed in the "*execution of the plan.*"

The question of profit, concerns the bookseller alone: as to the society, we have already stated, that no provision was made for it in the arrangement, except the one mentioned for the purpose of paying agents: and even that, seems most likely to prove inadequate for the purpose. As to individual members, there cannot arise a combination of circumstances, which can by any possibility, make the society a source of profit to one of them. We feel a sense of degradation in making these declarations; but the same feelings, which have led us to expend money, and labor, and care, and time, upon this enterprise, and which alone, induce us to notice the charges which we are now answering, also constrain us to declare, to those for whom we profess to have labored, that, with whatever degree of wisdom our measures have been conducted, or with whatever success they may have been crowned, the hands which have labored in their accomplishment, are not grasping after pecuniary profit.

One more remark on this portion of the subject. Your correspondent intimates, that the library published is a contrivance to pass off the old stock of the publishers as new publications, issued under the "execution of the plan," contained in the society's prospectus. Now, to say nothing of the probability, that men of such standing as those who formed the executive committee, by whom the library was published, should volunteer to blast their own characters, in order to assist the publishers in so admirable an enterprise; and should be guilty of "little less than downright deception," in order to do so, without the most distant possibility of reaping any profit themselves, it seems a little strange, that it did occur to your correspondent, that, if any deception, such as he alluded to, was ever dreamt of, the fraud must have been as clumsy in its management, as it was gross in its conception; that they who were profligate enough to practice gratuitous roguery, in order to help a publisher off with his old stock, were also senseless fools enough, to send forth to the world, in every book they published, the obtrusive evidence of their deceit; that they wished to pass off works as new publications, whose every title page declares, that they were not so; and whose every preface states that they were existing publications. [From the Executive Committee.]

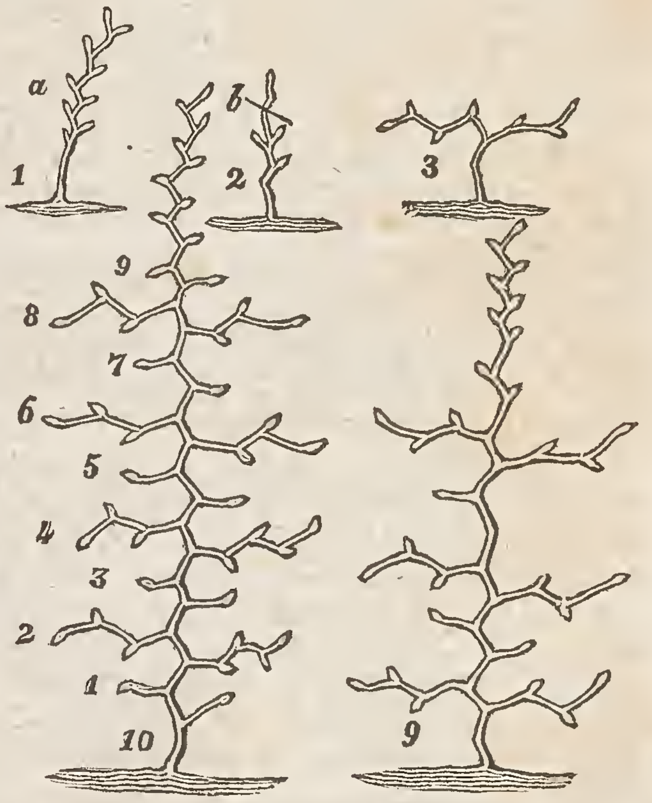
EXTRACTS.

Grape Culture.

[*From Wilson's Economy of the Kitchen Garden.*]

There are only two methods generally practised for raising grapes in this country, on trellises and arbors, and by the support of stakes, as in most vineyards. The former is much practised about towns, and with which we shall commence our directions on the best mode of training. But in the first place it will be necessary to say something about the preparation of the ground to receive the plants; for unless it be put in good order, it cannot be expected that the vines will thrive. Therefore, whenever vines are to be planted, the ground should be trenched to the depth of two full spades at least, and to as great an extent on each side of the place where the plants are to be set, as the situation will admit of If the whole garden can be thus trenched, so much the better. And in performing the trenching, a good supply of short dung should be well incorporated with the soil, which, if poor, should have the thickness of one foot of horse and cow dung laid all over it, and mixed in it in the trenching. This should always be done, if possible, the fall before planting; and by being well turned over with the spade early in the spring, would be in fine order for receiving the plants. Great care should be taken in removing these plants never to suffer their roots or small fibres to be exposed to the air so as to become dry. And the hole to receive them should be made sufficiently large to admit them freely at their full length, and should all be placed as nearly as possible about the same depth below the surface, as they were before they were taken up. No plant is easier to train, or looks better on a trellis or arbor, than the grape vine; and we would recommend either of the following modes. The first is calculated for a scale, where the plant is to cover a space eight feet in width, and of any height, from eight feet to eighteen or more.

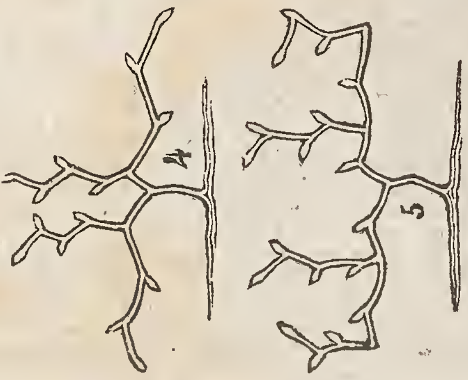
[Fig. No. 9.]



No. 1, on the plate, is a representation of the plant when set out, of one year's growth from the cutting, and is to be cut off to one good bud, as at *a*. The lower bud is seldom counted, and only the upper bud is to be allowed to produce one shoot; the young buds on this shoot will many of them shoot out in the course of the summer, which should be pinched off.

No. 2 represents the plant of one strong shoot, one year after being planted, and it is to be cut down to two good buds, as at *b*, about fifteen or eighteen inches high from the ground. The shoots from these two buds are to be trained to a trellis, horizontally, to a distance of four feet, and then their ends pinched off, as we intend the plant to fill a space in width of eight feet.

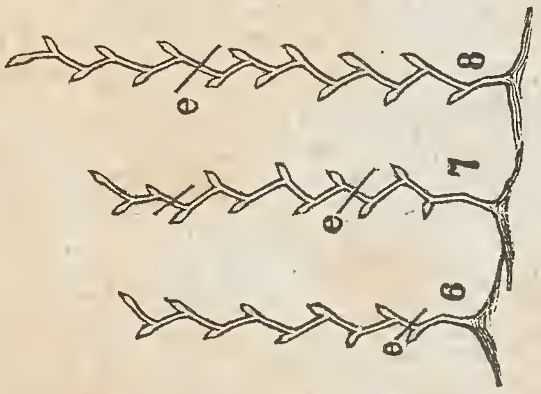
No. 3 represents the plant two years after setting out, with the two last years' horizontal shoots, as they must be cut into three good buds. The two buds next to the stem are to be allowed to shoot and grow upright as high as they please, to be tied up to the trellis, and the end buds to be trained horizontally, to the limits of three or four feet distance, and again pinched off.



[Fig. No. 10.]

No. 4 represents the plant three years from setting out, with its two last years' upright shoots, as they must be cut down to four good buds, which are this year to be allowed to bear fruit, and the horizontal branches cut into three good buds; their shoots are all to be trained upright, which will complete the head of your vine, with eight branches, at about one foot apart.

No. 5 represents the vine four years after setting out, with the two centre branches that bore fruit last year, as they must be cut down near to their origin. The two next cut down to four buds for bearing fruit. The next two to one good bud, for producing one good wood shoot. The next and last two, to three buds, for bearing fruit. Its regular culture afterwards is, to cut four of the branches low down, and to leave four longer to bear fruit alternately, always allowing the branches that bear fruit the one year to be cut down for recovering a good shoot again for bearing the next. The other mode of training, is called horizontal training, but may be extended to any height or distance you please, so long as you retain the leading shoot, or it may be confined to a very low space by cutting it off.



[Fig. No. 11.]

No. 6 represents the plant when set out, the same age as the other; to be cut also to one good bud, as at *c*. This bud to be allowed to produce one good shoot.

No. 7 represents the plant one year after setting out, to be cut down to three good buds, as at *d*. The shoot from the upper one of which is to be trained upright, and the two lower ones are to be trained horizontally.

No. 8 represents the plant two years from setting out. The leading shoot of which is to be cut down to nine buds, as at *e*. The upper bud to be allowed to shoot upright, and all the others horizontally; four feet from each side. The two last years' horizontal ones cut as they must be to one good bud, its shoots to be trained as it was last year.

No. 9 represents the plant three years after setting out, with its branches cut as they must be. The two lower ones to three good buds for bearing fruit. The next two cut to one good bud for wood. The next two, to three for fruit. The next two, to one. The other two to three, and the leading one again to nine. The upper bud to have its shoots continue upright, the other eight horizontally.

No. 10 represents the plant four years from setting out, with its branches cut as they must be. The lower two to one good bud; the second two to three buds; the third two to one; the fourth two to three; the fifth two to one; the sixth two to three; the seventh two to one; the eighth two to three; the ninth two to one; and the leading shoot to nine buds. All to be managed in the same way as those of last year. And in this way you may continue your plant as far as there is room; when that it is terminated, cut off your leading shoot, and regulate all the horizontal branches so that they may bear fruit and wood alternately to the end of the grape vine's existence.

It may be necessary to observe, that in the first mode described for training the vine, the two horizontal branches or arms to support the upright shoots, are intended to extend four feet from each side of the main stem; and on each of them are to be selected four upright branches, which will make them about a foot apart. It will be necessary to rub off any intermediate buds, so as to regulate them, to be placed at proportionate distances. And after they are once cut down to one bud, the next year's cutting down would be a joint higher, and this may be safely allowed for a year or two; but whenever they get too far above the arms, by cutting down to the lowermost new bud, they must be cut down on the old wood near to their origin, and only one good shoot allowed to grow; any other bud to be rubbed off. And the same rule must be observed in cutting in all the branches of those trained altogether on the horizontal plan. And in directing nine buds to be left on the leading shoot, it is only intended in case the plant be very strong and vigorous; should it not be so, it would be better to cut it to five, or even three buds, in which case there would be only one or two branches to be trimmed horizontally on each side, instead of four, as exhibited on the plate; and the choice of these numbers should always be regulated by the cultivator according to the actual strength and condition of his vine. And the same discretion is to be exercised in leaving the number of buds on the bearing branches, from three to four, to double that number, when his vine is strong. But the mode of cutting them in after bearing one year, and the continuation of their regular number and distances are seldom or never to be altered. Every bud of those left bearing, sends out young shoots which produce the fruit, and these must all be neatly tied up to the trellis; but all the lateral shoots from the other, constantly rubbed off. Perhaps no plant bears the knife better than the grape vine, nor can there be any thing more simple, easy, or entertaining, than the training of it, according to those principles which we have endeavored so plainly to describe. Those vines trained over arbors generally have their heads formed higher, but the principle of training all their parts so as to be regularly supplied with fruit and wood-bearing branches, is precisely the same as those described above. The great error that most inexperienced cultivators fall into is, their neglecting to cut cut down, in time, into the old wood, or their regularly selected branches: and suffering laterals to extend from all parts of their vine, they soon let it run into the wildest confusion. In all such cases the only remedy generally is, to cut off the whole concern, to that proper position upon the old wood where the head ought to be formed, and regulate the whole anew.

---

*Moneys received up to 23d of March, in sums of five dollars and over. The total receipts are included from post-offices marked with an asterisk.**
